INDEX TO VOLUME VIII.

The asterisk (*) denotes that the subject is illustrated.

- Abelia floribunda..... 273
- Abies Cilicica..... 295
- Abutilon, Souvenir de Bonn..... 387
- Acacia pubescens..... 25
- Acacias..... 499
- Acanthophorus crinita..... 487
- Acanthus longifolius..... 278
- Accumulation in the garden..... 28
- Acer cissifolium..... 447
- insigne..... 220
- Negundo..... 502
- Pennsylvanicum..... 396
- Achilleas..... 396
- Achimenes..... 16
- Acidanthera bicolor..... 220
- Aconites..... 366
- Aconitum Fisherii..... 466
- Acorns, germination of..... 6, 105
- Acroclinium roseum..... 255
- Adenocalymna comosum..... 179
- Adiantums..... 456
- Adlumia cirrhosa..... 117
- Adonis vernalis..... 179, 197
- Adulteration of canned vegetables and fruits..... 68
- Æschynanthus Hildebrandii..... 304
- Agave Huachucensis..... 184*
- Utahensis..... 384*
- Agaves in Southern California..... 228
- Aglaoisma commutatum..... 428
- pictum..... 416
- Agricultural experiment stations..... 401
- Agriculture, coöperative..... 451
- elements of..... 500
- the year-book of the department of..... 421
- Agropyrum repens..... 103
- vulgare..... 103
- Ailanthus..... 503
- in the west..... 122
- Air drainage..... 306, 378
- Akebia quinata..... 205
- Alberta magna..... 113
- Albizia occidentalis..... 479
- Aletris farinosa..... 283
- Allamanda Hendersonii..... 337
- Allen, C. L., articles by..... 438, 458
- Alnus rugosa..... 493
- Alocasia Johnstonii..... 426
- Alströmeria aurantiaca..... 288
- Alströmerias..... 317
- Althaea officinalis..... 403
- Alvord, William, article by..... 38
- Alyssum saxatile..... 214
- sweet..... 106
- Amaryllis, cultivation of..... 56, 86
- Ammophilà arundinacea..... 412
- Anæctochilus Sanderianus..... 454
- Ananassa sativa variegata..... 355
- André, Edouard F., sketch of..... 310
- Androgynous flower-clusters..... 222*
- Andromeda Mariana..... 154
- speciosa..... 185
- Anemone blanda..... 164
- Scythinica..... 183
- Japonica..... 136, 170, 229, 288, 487
- Lady Arildiana..... 85
- nemorosa Robinsonia..... 216
- sylvestris..... 216
- Angraecum sesquipedale..... 86
- Annuals for the garden..... 97, 106, 117, 255, 256
- Antirrhinum majus, a variety of..... 120
- Aphelandra orientalis punctata..... 514
- Apple crop, western..... 478
- orchards of western New York..... 248
- unproductive..... 48
- Red Beitingheimer..... 390, 428
- Canada or Old None-such..... 10
- scab in Nebraska..... 28
- Scott's Winter..... 200
- the Hibernal..... 349
- the Senator..... 520
- Apples, best English..... 474
- color bands on..... 439
- frost injuries to..... 417
- good varieties..... 428

The Forests of the National Domain.

THE small company of forward-looking people who, in the face of almost universal apathy, had been for years urging the necessity of some rational system of management for the forests on our national domain, felt greatly encouraged ten years ago when President Arthur was moved to mention the subject in one of his annual messages. We have no systematic forest-policy yet, not even the beginning of such a policy, but we are no longer surprised or unduly elated over the fact that men in places of high authority consider the matter worth talking about, at least. President Cleveland, like his immediate predecessors, in his message to Congress, which assembled last month, strongly advised that some adequate protection should be provided for the areas of forest which had been reserved by proclamation, and he also recommended the adoption of some comprehensive scheme of forest-management. He condemned the present policy of the Government of surrendering for small considerations immense tracts of timber-land which ought to be reserved as permanent sources of timber-supply, and urged the prompt abandonment of this wasteful policy for a conservative one, which should recognize in a practical way the importance of our forest-inheritance as a vital element of the national prosperity.

The House of Representatives, too, has taken prompt action upon Mr. McRae's bill, entitled, An Act to protect Public Forest Reservations. The provisions of the bill are simple. It authorizes the employment of the army to patrol these reservations, as has been done effectively in the Yellowstone Park and in the Yosemite Valley, and it empowers the Secretary of the Interior to make regulations in regard to their occupancy, to utilize the timber of commercial value they contain, and to preserve the forest-cover from destruction. It also empowers the Secretary of the Interior to cut and sell timber on non-reserved lands under the same rules as those made for the forest reservations, provided that it shall be first shown that such cuttings shall not be injurious to the public in-

terests. The bill had some unfortunate features, but any system which regulates the use of public timber is better than the indiscriminate plunder that has been going on hitherto, and the authorization to use the military for protective purposes is altogether commendable. The bill was amended, however, so as to strike out, if we understand it correctly, the provisions relating to non-reserved lands, and it restricts the sale of timber on the reservations to trees that are dead or mature, thus limiting skilled forest practice, instead of authorizing trained foresters to make their own selection, and, worse than all, it grants free supplies of timber from the reservations to miners and settlers.

It is to be hoped that when this measure comes before the Senate that its original features will be restored. In its present form it does little more than to expose the timber on the reservations to new dangers. We are judging, it is true, from the newspaper accounts, and the published text of the bill may show that the amendments are not so bad as they seem. If military protection is assured, that is one step forward, but if such protection is made possible only when the War Department shall consider it worth while, it is a very short step, indeed. No doubt, any measure which gives the assurance of efficient policing of the reservations, or efficiently controls the cutting of public timber, is to that extent a gain, but we certainly want something more definite and decisive than the McRae bill as it now stands.

And, while measures of this sort are being prepared and pressed for passage, why shall we not take immediate steps to examine this magnificent forest-property of ours in a more thorough manner than has yet been done, so that we can obtain facts to guide us in framing future laws, or, at least, to enable us to administer them intelligently? Seven years ago we urged the withdrawal of all these lands from sale until a comprehensive report should have been made by some commission capable of deciding what lands to sell and what to hold forever in forest, and we then proposed that, pending such a report, they should all be put under military protection. Why not provide for such a commission now, and begin the investigation at once? This work would not interfere with the adoption of any protective policy, and certainly we can get no laws which go farther and deeper, and furnish a comprehensive system of forest-management until we have secured possession of forests to manage. The appointment of such a commission need not be deferred until the passage of a protective law. Its creation would be entirely independent of other action. The work of the commission certainly would not obviate the need of forest-protection. It would be in quite another field to furnish facts as a basis for future legislation which shall embrace a detailed management of the forests. If such legislation were devised at once, the very first thing done by the officials created under it would be to make just such a forest-survey as a commission would make. This means that the appointment of such a commission as we contemplate would not disturb the administration of any law, but would in every way be in harmony with it, and help to carry out its spirit.

The nation holds these magnificent forests in trust for future generations. We certainly cannot know too much about their extent, their value and their character, and we cannot learn these things too soon. No Congressman who opposes other forest-laws need object to the inauguration of such a survey, because a commission can do nothing except to disseminate knowledge and furnish facts as a foundation for future action. Even if every recommendation of the commission should be rejected, we can think of nothing which would be a more powerful stimulus to public opinion than a comprehensive report upon our forest resources. The discussion which would be aroused by such a report, with its accompanying recommendations, would be an educational force of the highest value, and our only hope for legislation, immediate or in the future, depends upon the creation of such a public sentiment as will compel action.

Utility and Landscape.

ONE of the most important of problems in landscape-art is the reconciliation of structural utility with the beauty of scenery. It would seem that the problem would solve itself if every structure could be built so as to be in the highest degree both durable and practical. The Romans were not an artistic people, and in their great engineering works, like bridges and aqueducts, it is probable that they gave little thought to the æsthetic effect which such constructions would produce. But the rules that experience has shown to be the proper ones to follow in masonry are those that combine substantial construction with harmonious relations of parts to each other and to the mass, so that good proportions in line and form are always secured. Hence, the Roman works which survive in many parts of Europe, by reason of their stable engineering qualities, are almost invariably picturesque and beautiful features of the landscape. And to-day even the rudest stone bridges in the New England countryside, whether dating back for a century or of recent origin, never fail to delight the eye by fitting naturally into the elements of the landscape.

Doubtless the reason that the average wooden building is so ugly is that we have not yet learned the requirements for the most suitable forms of wooden construction, and the same may be said of such engineering works of iron and steel as the hideous railway bridges that mar the landscape of this country from ocean to ocean. The old-time farmhouse, with walls shingled and weather-beaten, seems to belong to its surroundings as naturally as a lichen-covered rock, and where curved lines are employed in metal construction, as in the great buildings of the World's Fair at Chicago, the effect of aerial grace in the fine, light springing lines is often fascinating in its charm, and the magnificent scene-building of that dream of one summer demonstrated its possibilities for artistic agreement with classic forms in architecture.

It is so frequently the case that the simple expression of the inherent purpose of a structure in the most direct way produces the most agreeable artistic results, that this may be said to be the rule to be observed in aiming for those results. One of the most familiar examples is that offered by the great coal-sheds, which are such prominent features of the water-front in our maritime cities. Beauty is the last thing regarded in their construction. Yet they form elements of remarkable interest in the waterside landscape; built to perform a certain necessary service, everything about them is planned to meet the requirement in the most straightforward way. The huge bulk of the structure, designed to contain enormous masses of coal, is impressive in its own enormous mass; the projections, towers and scaffoldings, built just where they are wanted, are often highly picturesque in their effect, lined sharply against the sky, and reflected in the water; the surfaces, grimy as they are, are not offensive in their hues, and are marked by rich plays of light and shade in the shifting sunshine, and by beautiful atmospheric effects, varying with the conditions of haze and mist, or of crystalline air; and the steamers, barges and sailing vessels, always lying alongside, complete the picturesque interest of the scene.

The way in which maritime commercial conditions may enter into the charm of a landscape is exemplified in a scene like that at the head of navigation on the Neponset River, in the Boston suburbs, where the fresh water of the stream comes tumbling over a dam into the placid salt flood of the estuary and furnishes motive-power to a factory on the bank; on the other side the long slope of a hill is covered with handsome suburban villas, and at a busy wharf the slender spars of vessels rise against the background of a bit of woodland close by the water, and wide levels of salt-marsh border the distant reaches of the river in its course to the bay. This incident of commercial utility in a landscape of exceptional beauty, far from form-

ing a disturbing element, gives a heightening accent to the tranquillity of the scene.

There is a pseudo-æstheticism that affects to regard elements like these as vulgar and commonplace. But genuine artists take them seriously into account as of positive value in a landscape. When the question of designing the Strandway, the handsome shore-drive of two miles, now under construction, along the Old Harbor shore of Dorchester Bay, came before the Boston Park Commission a serious obstacle presented itself in the shape of a great coal-wharf, with an elaborate modern equipment. Mr. Olmsted reported that such a feature was by no means an undesirable thing; it properly belonged to the maritime spectacle, which the drive was designed to command, and would lend interest to the scene. In consequence, instead of taking the wharf, at a cost of probably more than \$200,000, the drive was designed so as to pass outside and cross by a drawbridge a channel giving access to an enclosed dock. In the design of the esplanade and drive for the Cambridge bank of the Charles River, a similar problem of dealing with an interval of wharf property is solved by carrying the way behind the wharves in a manner that does not interfere with convenient access to them.

A problem of utility more difficult to solve is that of the windmill. The old-fashioned windmill of four arms, like those of Holland, which occasionally survives along the New England coast and on Long Island, is always a picturesque element in the landscape. Two of these mills form attractive features of the beautiful "Anlagen" which have taken the place of the ancient fortifications at Bremen. But these clumsy old contrivances are of small efficiency beside the modern devices which have made wind-power of such a varied utility that their sales in the United States are numbered by the hundred thousand each year. Unfortunately the too definite circles which their lines present make it impossible for them to be beautiful features of the landscape. With their enormous tails, or rudders, they give the effect of some form of prodigious insect hovering about the country.

In many parts of the United States the modern windmill is now as distinctive a feature of the landscape as its prototype is in Holland, and is even more numerously represented. It ministers to the convenience, and lightens the labors, of millions of people. In certain villages on Cape Cod, for example, almost every house whose owners are fairly prosperous has its windmill and is supplied with all the conveniences in the way of running water that a city family enjoys. And in Winchester, a Boston suburb of several thousand population, the high service division of the municipal waterworks is supplied by a large windmill at a very considerable annual saving over steam.

With the perfection of the storage battery its power to generate electricity for domestic and other use will insure for the windmill a much wider employment in the future. It furnishes the cheapest form of all motive-power. With a device of such extraordinary value, effecting as it does now an economy of many millions of dollars annually, it would be folly to think of discouraging its use because of æsthetic shortcomings. The true course is to see what may be done to improve it in this respect and give it a form which will unite efficiency with artistic character. To attain this end, economy of construction must be kept in view as the main consideration, for without this popularity could not be looked for. In existing devices a remarkable economy is already reached. But, owing to its inconstancy, wind-power has not been studied as other forms of mechanical energy have been, and it is not unlikely that forms may yet be devised that at a given cost may develop a much greater amount of power than is obtainable from devices now known. The hope is that the ends of use and beauty may be reconciled in the shape which these more efficient forms may take. The artist and the engineer should coöperate for this purpose. If a windmill, acting in a horizontal plane, could be

made as efficient as the perpendicular form now prevailing, it might be practicable to give it a design good in proportion, perhaps tower-like in character, and in harmony with the landscape of which it must necessarily be a conspicuous feature. Possibly much may be done to improve the perpendicular form; but it must evidently be developed upon quite different lines from the old-fashioned windmill, for lightness and simplicity in construction are required in order to secure the greatest amount of energy at a minimum of cost. The circular form is, of course, essential to efficiency, and must be retained. In lightness and strength great advances have been made by the substitution of steel for wood. Still greater advances would seem possible by the use of aluminum, which, being extremely malleable, would seem to be the most suitable substance for very thin wind-surfaces. Being non-corrosive in nature the metal could be used in its natural color, and its light and silvery appearance might produce an agreeable, though novel, effect, not unlike the gleaming of white sails on the blue water. Again, much may perhaps be done to give the supporting structure a more graceful and attractive form, and a pleasing effect might be produced by the training of climbing plants over it. At all events, in view of the increasing prominence of the windmill in our landscapes, the subject seems worth the attention of competent artists.

Boston.

Sylvester Baxter.

Christmas in the Pines.

THE Pines just now remind one of Florida rather than of New Jersey. I never remember to have seen as much freshness in a ramble here at Christmas-time as now appears, and I can hardly realize that these are winter days. The foliage is so green and the berries so bright and plump that it is difficult to associate them with shriveling frosts. Not a flake of snow has fallen, and many warm rains have served to keep up the illusion that somehow this is a belated section of summer. The woods are always fragrant, but now they do not exhale the rich odor of fallen leaves, but the subtle, living aroma of growing Pine-trees, and the spice of shrubs and herbs, which is always so refreshing.

The creeping plants have taken on some of the most brilliant hues. The slender Running Blackberry, *Rubus hispida*, is a study; some of its leaves are a brilliant scarlet, others purple and crimson, while many still retain their deep green hue. The low Sand Blackberry, *R. cuneifolius*, is also holding its leaves, but these are mostly green. The Swamp Rose, too, is green and full of bristly fruit; the Dwarf Wild Rose is conspicuous with its abundant smooth red hips and its persistently green leaves, and the Wild Strawberry covers the ground in places with a carpet of such varied color as to defy description. Some of the Thorns are holding their foliage as well as their fruit, especially *Crataegus uniflora*, which looks much like an evergreen with its thick shining leaves.

But the crowning glory of the Pines at this time is found in the Heath and Holly families. The deep green, glossy foliage of the Laurel was never more handsome than now. Cassandra is showing its flower-buds in all the axils of the small evergreen leaves. The Sand Myrtle, *Leiophyllum*, another pretty little shrub among the Heaths, has an abundance of dark shining leaves, and when not too crowded it has the aspect of a much-branched miniature tree. *Gaylussacia dumosa* is still covered with its thick glossy leaves, quite like an evergreen, and so are many of the Andromedas and Leucothœs. Possibly the long drought of summer has something to do with the unusual persistence of the leaves of the deciduous shrubs. When the early autumn rains came, many of the spring-flowering species blossomed, and new leaves put out, which are not yet ready to loosen their hold. But many of the old leaves, too, still remain on the branches as if they had determined to become evergreen or had forgotten to ripen and fall.

The trailing plants in the Heath family are no less attractive. The Cranberry, with its red fruit and lustrous little leaves running through beds of moss, has a sprightly look that harmonizes well with the wild flavor of its berries. The Trailing Arbutus is showing its clusters of buds, all ready for blossoming next spring. The berries of the Creeping Wintergreen were never larger than they now are and never glowed with a deeper scarlet, and the leaves of the running Chimaphilas were never more thick and substantial. The ever-welcome Holly displays its brilliant berries in clusters of unusual size, and its relatives, *Ilex verticillata* and *I. laevigata*, with fruit equally bright, have never carried a heavier Christmas crop, while the shining leaves and black fruit of *I. glabra* are quite as attractive.

Cone-bearing sprays of fragrant Pine, and the Cedar, with its small blue-gray cones, and the fruit of the Sweet Gum in handsome round heads on long stalks, can be arranged so easily into beautiful combinations that one is tempted to carry them away by the armful for Christmas decorations. The Mistletoe, with its yellowish green leaves and white berries, is here, too, and has a fascination for most people, but I must confess that many of the other evergreens in the Pines are far superior to this in my esteem. Some of the Lycopodiums are highly ornamental, especially *L. obscurum*, which is so like a little tree, and *L. alopecuroides*, with its more stout and thicker stems, can be woven with good effect into almost any arrangement of Christmas green. The long, curved, grass-like leaves of *Xerophyllum* are effective, too, when mingled with other evergreen leaves, and so are the infinitely varied seed-vessels in their sober colors, the cones of the Pine family, Rose hips and other fruits, in bright tints, all of which the Pines now offer in unstinted measure.

Foreign Correspondence.

London Letter.

SCHOMBURGKIA RHINODORA, var. **KIMBALLIANA**.—This plant was named by Reichenbach in 1888, in compliment to Mr. W. S. Kimball, of Rochester, New York, in whose collection it first flowered, producing "a long-branched raceme bearing numerous light purple flowers." A plant of it was shown in flower last week by Messrs. H. Low & Co., at the meeting of the Royal Horticultural Society and received an award of merit. It has narrow pseudo-bulbs eight inches long, hollow, as in all Schomburgkias, and the leaves are six inches long, thick and leathery. The scape is erect, two feet long, in this case bearing only one short branch. The flowers are clustered about the apex of the scape and each one is two inches across, with narrow oblanceolate segments colored bright purple, with a dark crisp margin on the front of the folded lip. It belongs to the same section of the genus as *S. Tibicinis*, and is probably as difficult to flower.

SERRATOSTYLIS MODESTA.—This is a new genus of Orchids, which first flowered in the collection of Sir Trevor Lawrence, at Burford Lodge, in February of last year, and was first described in the *Kew Bulletin*, 1894, p. 158. It was sent to Mr. O'Brien from the Andes of New Granada by Mr. F. C. Lehmann. Mr. Rolfe, who described it, places it next to *Brassia*, although in some of its characters it resembles *Trichopilia* and *Ornithocephalus*. It has linear-oblong smooth pseudo-bulbs two inches long, each bearing a single, broadly lanceolate leathery leaf, seven inches by two inches. The scape, which is developed from the base of the mature pseudo-bulb, is nodding, seven inches long, crowded with flowers in which the segments are equal, spreading, forming a star an inch across, colored light red-brown, margined with pale yellow, the small narrow lip being whitish yellow, with a few purple lines. The column has a pair of wing-like auricles and fimbriated top and an elongated beak-like rostellum. The linear front

lobe of the lip and this elongated rostellum are the most peculiar characters of the genus. A figure of it, prepared from a second plant exhibited at a meeting of the Royal Horticultural Society a few weeks ago, is published in the *Gardeners' Chronicle* this week. It belongs to the modest or purely botanical section of cultivated Orchids, and was accordingly awarded a botanical certificate by the Orchid Committee.

CYMBIDIUM TRACEYANUM.—Baron Schröder again electrified the Royal Horticultural Society by showing this week a magnificent inflorescent from his unique specimen of this grand Cymbidium. It was about three feet in length and bore twenty-one flowers. There is an opinion held by some authorities that this plant is a natural hybrid between *C. giganteum* and *C. grandiflorum* (*Hookerianum*), and certainly the character of the flowers gives support to this view of its origin. As the two supposed parents have, I believe, already been successfully crossed, we shall know in time. In any case, *C. Traceyanum* is the king of all Cymbidiuns.

KLUGIA NOTONIANA.—This is a pretty greenhouse plant which deserves to be better known. Probably it has hitherto failed to attract the notice of horticulturists because it has always been treated as a stove plant and has proved unsatisfactory. In a cool house, however, it behaves very differently. There are plants of it at Kew now a foot across crowded with healthy foliage, and the branches are terminated with racemes of flowers something like Achimenes, but the corolla has one large front lobe, a labellum, in fact. The color is a rich gentian blue, with a blotch of yellow at the base of the lip. In Ceylon this plant is common at an elevation of 5,000 feet, occurring in great abundance in wet places in gullies, and, according to Mr. Nock, of Hakgula, it is always in flower. The natives eat the stems boiled, and they are also used in making curries. *K. Notonian*a is described in the *Flora of British India* as an annual with small flowers. At Kew it is a perennial, and the corolla is over an inch across. It is a Gesneriad and is allied to *Boea* and *Cyrtandra*.

HARDY BAMBOOS.—A series of articles on these plants is appearing in *The Garden* from the pen of Mr. A. B. Freeman Mitford, C.B., M.P., who has a large collection of hardy Bamboos in his beautiful garden at Batsford, near Stratford-on-Avon. Mr. Mitford has been collecting and studying Bamboos for some years, and his observations are rich in practical suggestions for the cultivator as well as for the botanist. I believe it is his intention to republish his articles in book form, with illustrations. Bamboos for the outdoor garden in England have only lately received attention, but already the number that can be grown out-of-doors is extraordinary. At Kew there are between forty and fifty species and varieties which have stood our climate for two or three years. At Batsford the Bamboos are planted in large groups in various positions in the landscape, and they promise to produce in a year or two an effect such as has never before been seen in England.

A LIBERAL GIFT.—A winter garden, which is to cost ten thousand pounds, has been offered by Mr. Henry Yates Thompson (whilom proprietor of the *Pall Mall Gazette*), and accepted by the Liverpool City Council for its largest and handsomest park—namely, Sefton Park. The house is to be octagonal, one hundred feet in diameter, with a curvilinear roof and a central dome rising to a height of seventy feet. The interior is to be planted with Palms, Tree-ferns, Bamboos, Camellias, Rhododendrons, etc., and the whole is to be planned with a view to its affording convenient shelter to frequenters of the park in showery weather as well as for a pleasant promenade in winter. The only condition attached to this generous gift is one which might be looked for from a man of Mr. Yates Thompson's well-known advanced views—namely, that it should be open on Sundays as well as week days.

HARDY TREES AND SHRUBS.—The collection of trees and shrubs grown in the open air at Kew comprises some three thousand species. A list of them has been in preparation

for some time, and the first part of it is now published as "the first of a series of hand-lists of the collections of living plants cultivated in the Royal Gardens, which it is intended to issue from time to time. . . . It is hoped that these lists will be of value in establishing an approximate standard of nomenclature, which is often much confused in gardens, and too frequently erroneous." The part now published contains all the Polypetalæ (*Ranunculaceæ* to *Cornaceæ*), and, with the index, fills 148 pages. It is published by Messrs. Eyre & Spottiswoode, the price being eighteen-pence. [A notice of this book appears on page 9 of this issue.—Ed.]

In 1768 there were 488 hardy trees and shrubs grown at Kew, where, even then, an arboretum had been a feature for some years. The collection gradually grew until in 1845 over one hundred acres of what was then known as the "Wilderness" were added to the gardens with a view to forming a national arboretum. In 1850 a nursery for hardy trees and shrubs was formed, and in 1870 a new pinetum was started. "The late Director, Sir Joseph Hooker (1865-1885), spared no pains to amass the most complete collection which could be formed of hardy woody plants. These were obtained from public and private correspondents and establishments at home and abroad, partly by purchase, partly by gift and exchange." The present Director, Mr. Thiselton-Dyer, has continued the work of planting and improving the collections, which are now unquestionably unrivaled in regard to their comprehensiveness. Kew is not an ideal place for an arboretum; it is too near the bad influence of London smoke, and the soil is poor, in some places mere gravel, with the thinnest crust of soil. Consequently some of the specimens are not of the healthiest character, still, taken as a whole, the collection is certainly without a rival.

Some of the plants included in the list are only hardy in sheltered positions, such as against walls, and a few, although they are tried again and again, have invariably perished in severe weather. Such, for instance, are *Rosa gigantea*, *R. berberifolia*, *Illicium floridanum* and a few others. Generally, however, it may be said of all the plants included in the list that they are hardy at Kew.

The nomenclature is, of course, that of the *Genera Plantarum* and the *Index Kewensis*. It is to be hoped, now that we have a standard list, all who are interested will adopt it, and, by so doing, reduce the present woeful confusion in the names of cultivated plants. Horticulturists want a name only for a very simple purpose, namely, to identify the plant by, and it is desirable that the plant should bear the same name in every country the whole world over. This is asking a great deal, but it is certainly the end to be aimed at.

In the list under notice there are 994 species and 640 botanical varieties, and these have no less than 2,127 synonyms. It has been a task of considerable difficulty, entailing much labor and care, to bring this lot of names into order, and Mr. Nicholson, the curator, whose knowledge of trees and shrubs is unrivaled in England, deserves the thanks of all who are interested in these plants for his share, the principal portion, be it said, of the work. It is only with the vast resources of Kew that such an undertaking could have been brought to a successful issue. When complete, and it is to be hoped that the remainder will soon be finished, the list will be of the greatest use. Each name is followed by the authority, a reference to a figure and the country of which the plant is a native. Then follow the synonyms. The names are printed only on one side of the leaves, this leaving space for additions.

London.

W. Watson.

The dry rustle of the withered Oak-leaves is the voice of the wood in winter. It sounds like the roar of the sea, and is inspiriting like that, suggesting how all the land is sea-coast to the aerial ocean. It is the sound of the surf of an unseen ocean breaking on the forest like water on sand and rocks. It rises and falls, swells and dies away with agreeable alternation, as the sea-surf does.—*Thoreau's Journal*, January 2, 1859.

New or Little-known Plants.

Streptocarpus Dyeri.

THIS is a hybrid between two of the largest monophyllous species, *Streptocarpus Dunnii*, an account and figure of which will be found in GARDEN AND FOREST

through the year till within a few weeks ago. The accompanying illustration on this page is from the photograph of a specimen formed of three plants grown together in a pan, and which, when at its best, was one of the handsomest and most striking flower pictures I have seen for a long time. Each plant had a single leaf two feet long and

Fig. 1.—*Streptocarpus Dyeri*.

(vol. iii., page 609), and *S. Wendlandii*, noted in the last volume of GARDEN AND FOREST (page 134). Both species were in flower together in the summer of 1892, when they were crossed with each other, the seedlings thus obtained flowering in the spring of this year and on all

fifteen inches wide, colored rich olive-green above, vinous purple below, and clothed with soft hairs. The bright red-purple flowers formed a sheaf nearly two feet high. One specimen, a single plant, had an enormous leaf, from the base of which sprang six erect stout racemes, the tallest

thirty inches, the shortest twelve inches high, all crowded with flowers. There must have been at least one hundred open together.

When properly treated this is a noble plant, quite exceptional in its beauty and habit. Seeds sown in March will produce flowering plants by April of the following year. They should be grown in light soil in an intermediate temperature and a sunny position. In America they would probably grow well and flower freely in the open air if treated as bedding-plants. The species ripen seeds freely, but these first hybrids do not. *Streptocarpus Dyeri* has not ripened any seeds with us, and, as the plants perish after flowering, to obtain the hybrid again the cross must be repeated. This, fortunately, is easily done. All the monophyllous species of *Streptocarpus* die after they have once flowered; the others are all perennial.

Plant Notes.

IRIS PALÆSTINA.—Well distributed in the Holy Land, there grows a little bulbous Iris of the Juno section, which flowers at this season. It has the usual ovoid bulb, with brown coating and persistent roots characteristic of the group. It can be flowered here only under glass. The small flowers are greenish yellow, not striking or specially attractive. The variety with purplish blue flowers known as coerulea is much more attractive and much resembles *I. alata*, but has not the winged claws of that species and is inferior in size. The showiest Iris of the season is *I. stylosa*, to which we lately referred (vol. vii., p. 454). This species, if strongly grown outside during the summer, will now provide a supply of attractive fragrant flowers in a cool house.

JACOBINIA MAGNIFICA.—This is one of the most floriferous plants of this season in the greenhouse. It is showy, too, and it is grown in quantities on account of its compact habit and its general usefulness as a decorative plant. Old plants grown on from year to year do not make such good plants as those that are raised annually from cuttings. Therefore, when they are done flowering they can be thrown away, except a few that should be kept as stock plants. Cuttings taken in March root easily with the aid of a little bottom-heat. When rooted they are put into small pots of rich open soil and placed in a moist warm house until the end of May. Then they can be planted out in the garden in a sunny position. They require a liberal supply of water during the summer, and attention must be paid to pinching the young shoots so as to make them stocky and keep them from flowering. If properly treated, by the end of August they make handsome little shrubby plants, and should be then taken up and potted in rich light soil. They should be syringed often until they recover from the effects of their change. When the nights grow chilly in September they should be placed in a cool greenhouse where they will get an abundance of light. In a short time they will be covered with large clusters of showy reddish purple flowers, which grow profusely at the ends of the branches, and the plants remain showy for a long time; the flowers do not last long after they are cut.

CROTALARIA LONGIROSTRATA.—Mr. Cameron writes that this plant is now attracting attention in a cool greenhouse at the Botanical Garden in Cambridge. It is a Genista-like plant, introduced from Mexico a few years ago, and is not plentiful in cultivation yet; but when better known, he thinks, it will become a favorite as a cool greenhouse plant. It is a rapid grower, and does not make a shapely plant if it is not pinched frequently when the young shoots are growing vigorously in summer. Well-grown specimens are clothed abundantly with ternate leaves, and the orange-yellow, pea-shaped flowers are produced in terminal racemes. The plants ripen seed and can be increased either by seed or by cuttings; those raised from cuttings in spring make good winter-flowering plants.

STIGMAPHYLLON CILIATUM.—This is a climbing plant from Brazil, and it is sometimes called the Golden Vine, from its

yellow flowers, which at once suggest those of an *Oncidium*, both in their form and in their color. It is a summer-flowering twiner, and it was once thought to require stove treatment, but ordinary greenhouse temperature is what it needs, and in our southern and central states it will flourish out-of-doors and bear its bright blossoms in great abundance. When planted in a greenhouse its flowers cover the young shoots, and in autumn, if it is cut back hard, it will at once begin to make new wood for flowers, which will appear as soon as the lengthening days bring enough sunshine. If it is left, however, and cut back but slightly in the greenhouse, it will bear a few flowers all winter long. This plant does better when planted in the ground than when grown in a pot, and during the hot weather it needs to be syringed quite frequently to overcome the red spider. It is easily propagated by cuttings.

Cultural Department.

Germinating Nuts and Acorns.

To the amateur planter no class of the larger seeds of trees and shrubs causes more disappointments and elicits as many questions as do the various kinds of fruits known as nuts. The cause is generally a lack of knowledge, of proper treatment, or carelessness. It does not seem to be generally understood, although the fact has been stated over and over again in horticultural journals, that many of these seeds retain their germinative power for a comparatively short time after maturity, unless they find the proper conditions for their preservation. The acorns of the White Oak, *Quercus alba*, for instance, often crack and sprout and show the so-called root before the fruit falls from the tree. If these acorns are gathered and allowed to dry for a few weeks before planting it is unlikely that any of them will grow. The same result follows in nature if they fall on ground which is hard and dry and continues so for some time afterward, but if the ground is moist the radicle or incipient root will soon enter it and be secured from drying, unless the soil itself should be deprived of moisture. What is true of the White Oak is true of other species, although often in a much less marked degree. Some of the Black Oak group, for instance, bear acorns which are slower in germinating and appear to preserve their vitality better under adverse conditions. It is destructive to the vegetative power of all acorns to collect them in the autumn and keep them uncovered in an ordinary dry room, to be planted in spring. But any of them may be preserved for months if simply packed or mixed with moist, but not wet, sand, soil or moss, and kept in a cool temperature, such as would prevail under a light covering of leaves or soil in the open air. Similar treatment must be given to Hazel-nuts, chestnuts and to Beech-nuts. In all cases care should be taken to mix in plenty of soil, or to place the nuts in layers so that they do not touch each other, and any tendency to heat and consequent molding should be guarded against. Butternuts, walnuts and Hickory-nuts will not grow readily, or at all, if allowed to become thoroughly dried or cured, although the kernels may preserve a fresh appearance for years after germinative power is lost. They will, however, keep their vitality much better and longer than acorns under the same conditions.

As a rule, direct planting in the open ground as soon as the seed is collected is to be preferred, wherever practicable, for most kinds of nuts and acorns. Among objections to this system are (1) the liability of the larger nuts to destruction by squirrels, of the thinner-shelled ones by mice and some other rodents, or by birds; and (2) the action of frost in heaving the nuts out of the ground. Where the predators can be guarded against, the heaving action of frost may be obviated by a covering of leaves or boards laid over the seed. Some growers aim to plant after hard freezing weather has set in, because there is then less liability to disturbance by animals. In this system of planting an extra quantity of seed is required to allow for failures or mishaps, just as is the rule with many field crops.

Walnuts, Hickories and Oaks generally form long tap-roots, and some persons consider it an advantage to have the seed planted where the trees are to remain permanently, as it is generally found expedient to cut the tap-root when transplanting. When the seed is planted where the tree is to remain experiments have shown that these undisturbed trees make a much faster growth, in their early years at least, than those whose main roots have been cut. In growing a limited num-

ber of these tap-rooted trees the seeds may be planted in shallow boxes, when the roots will take a horizontal direction on reaching the bottom of the box, and they may then be transplanted without much injury.

It is a very common mistake to plant nuts too deeply in the ground. From one to two or three inches is quite enough covering for hickory-nuts and walnuts, especially if the soil is compact. Enough soil to barely cover them will give better results than a covering six inches deep, provided the surface soil is not dry and is not allowed to become so until after the roots have penetrated the ground several inches. A few kinds of acorns will grow if merely left on the surface of moist, shaded soil, and most kinds will be sure to germinate if only the tips are pressed into moist ground and they are not allowed to dry. Enough soil to just cover the acorns is best in all cases. It will be found that a long descending stem, popularly termed the root, is produced before any ascending stem bearing leaves is visible; and for two or three years afterward the plants often seem to spend most of their energies in root-formation. This may be noticed particularly in the White Oak, where the roots will grow several times longer and much thicker than the part of the plant above ground. The apparent growth of the plant at this period seems very slow, but after a good root-system is established the development of the little tree is much more rapid.

The walnuts and Hickory-nuts and many kinds of acorns collected this autumn for planting, and which have not been subjected to unnatural drying, still retain their germinating qualities; but, if not planted at once, they should be placed where they will keep moist and cool during the winter.

Arnold Arboretum.

J. G. Jack.

Notes on Lilies.

AMONG the fifty or sixty species and varieties of Lilies growing here, there are three Asiatic species, which, for me, have had more interest the past season than others, possibly owing to the fact that they are rarer and more expensive than the average, but principally, I believe, from the fact that they have done so much better than I had reason to expect, judging from my experience with other kinds under similar circumstances. The first of these was the new *Lilium Henryi*, which I secured late in the autumn of 1893, and the others are *L. Nepalense* and *L. Wallichianum*, var. *superbum*, received with a second supply of *L. Henryi* early last spring. I obtained the bulbs from England, but they were not, as I understood, taken from a nursery, but had just been brought into England from their native soil. They must have traveled thousands of miles before reaching England, from which place they were reshipped, and by the time they reached me they must have been months out of the ground, and probably had been repacked two or three times. Yet they had not, apparently, suffered from their journey. They were in good order when received and showed no signs of decay. There was such a contrast between their appearance and that of some of the species from the Pacific coast, after a journey of only six or seven days, that I mention these items as among the distinct points in their favor.

There was little difference in the results obtained with the three species. They all came up in due time after planting, sent up good vigorous stems with healthy foliage, and, excepting two or three small bulbs that might not have bloomed had they been left in their original homes, bore good healthy flowers. *Lilium Henryi*, which was first discovered in the mountains of Ichang, of western China, a few years since, is especially vigorous in its growth. Its foliage is thick and healthy, and it seems to belong to a class as easy of culture as the Tiger Lily or common Meadow Lily. I cannot, of course, vouch for its hardiness, but even if it must be covered so as to exclude frost, or taken up in autumn, and, like other tender bulbs, wintered in a cellar, it is a great acquisition and should be in every good collection. Its flowers, in shape and size, are not much unlike those of the *L. speciosum*, and of a bright orange color, with a few purple spots. This Lily did not mature any seed here, possibly owing to the fact that it was planted in the spring, and was consequently late in starting. I have the bulbs covered to exclude all frost and look for much earlier flowers next year. I suppose this heavy covering is not necessary in the case of well-established bulbs, but since it is the most expensive Lily I have, I will postpone any experiments as to hardiness until my stock is larger, or until the price declines.

Lilium Wallichianum, var. *superbum*, is from the central Himalayas. The typical species is mentioned as a greenhouse plant in Nicholson's *Dictionary of Gardening*. It seems

that this variety is much more tractable in cultivation than the typical plant, and the flowers much superior in beauty. Mr. Goldring, in his London letter to *GARDEN AND FOREST* of July 24th, 1889, says of this Lily: "It is, unfortunately, not hardy, but will prove a superb plant for the greenhouse." If Mr. Goldring means that the bulb will not bear freezing, he is, no doubt, quite correct, but if he means that it is too tender for cultivation in the open air, my experience with it last summer would seem to contradict him. It certainly made a very thrifty growth with no better treatment than was given to other common kinds like *L. Canadense*, *L. superbum*, or *L. tigrinum*. The texture of its roots is very firm, and I think it will bear transportation, without injury, farther than most species. Its large trumpet-shaped white flowers, shaded with chocolate outside and delicate primrose-yellow within, are very attractive.

Lilium Nepalense, which bloomed in England for the first time in cultivation in 1888, is also a native of the Himalayas, and, like the other, is said to be a tender greenhouse plant. But it grew here with as much strength and bore as perfect flowers as any plant of *L. tigrinum* that had not been planted longer. The flower of this, though not so striking as some others, is, nevertheless, beautiful—white, with purple within at the base of the petals.

Charlotte, Vt.

F. H. Horsford.

Propagating *Ficus elastica*.

AMONG the more common decorative greenhouse plants there is probably none so hard to propagate as *Ficus elastica*. If only a few plants are wanted, they may be secured by mossing. This is done by removing a leaf from the shoot about a foot from the top, and making a cut from below the joint about an inch long, slanting in an upward direction and extending about half through the shoot. Sphagnum moss should be tied about the cut, and this must be kept damp. In about three weeks the roots will appear through the moss. The shoot should then be cut off just below the moss, and potted with the moss in a three-inch pot, and kept shaded for a few days until the roots get hold of the soil. If plants are wanted in larger numbers this method is too slow, as it is hard to obtain a sufficient number of points. The plan then is to cut the stem into joints about an inch long, leaving a leaf on each joint, and from the side of the joint opposite the leaf the bark and a small part of the wood should be cut. The joints should then be inserted singly into small pots filled with moss and a little fine sand, and these plunged in a propagating-case in a good bottom-heat and kept moist. They soon make roots, and eventually throw up a shoot from the base of the leaf. When their shoots are about two inches high they should be shifted into larger pots, using a compost of equal parts of loam, leaf-mold and sand, and plunged in bottom-heat as before. When fairly started they grow rapidly and soon attain size.

Tarrytown, N. Y.

William Scott.

Romneya Coulteri.—It is pleasant to learn from your issue of November 21st that this most beautiful wild flower of the Pacific coast has lived through the winter in northern New Jersey. My observation of the habits of the plant as found wild shows that it is a perennial with biennial stems. On strong plants the new growths produce flowers freely the first year, sparingly the second year, and then die away. After removal plants must become well established and vigorous before any flowers can be expected. Doubtless, the preservation of the new growths through the winter would add to the strength of the plant the next year. I am very hopeful that Mr. Gerard will be rewarded with flowers next summer, and if so it will be a triumph for eastern horticulture.

E. D. Sturtevant.

Protecting Peach-trees.—Many experiments have been tried in attempting to protect Peach-trees during the winter by covering them with canvas, corn-stalks or some similar material, or by applying some adhesive substance to the branches themselves. Such attempts have never proven satisfactory, however, and the only practicable means appears to be by laying the trees on the ground and covering them over with soil or coarse material of some sort. To many people this, like many other operations with which they are unfamiliar, seems a great task. Experience proves, however, that it is comparatively inexpensive in practice. In setting the young orchard on the college farm last spring this matter was kept in mind, and part of the trees were set with the roots spread out on opposite sides as much as possible, with the intention of laying these trees down every winter as long as they live, if it is found practicable to do this. At least, it is hoped to determine how old

a tree must be before it becomes too unwieldy to handle in this way. To put down these young trees this fall was a very simple operation. Fifty-five trees were laid down and snugly covered with about four hours' work, thus costing only about a cent a tree. Indeed, the ease with which it was done raises the question whether it would not be well to lay down all young trees for the first year or two, until they become thoroughly established and better able to withstand the winter. Of course, the cost will rapidly increase with each succeeding year until the trees reach their full growth.

Lincoln, Neb.

Fred W. Card.

Chorozemas.—These New Holland plants are worthy of a place in every greenhouse, flowering as they do at a dull time of the year, when the last Chrysanthemums have disappeared. They are easily cultivated and readily propagated. Short, firm cuttings, rubbed off with a heel and inserted in bottom-heat of seventy-five degrees now, will make nice plants in six-inch pots in a year's time. For compost, good fibrous loam two parts, leaf-mold one part, and a good admixture of sharp sand will be found suitable when the plants reach a moderate size; some well-dried cow-manure can also be mixed in the soil with advantage. The pots should be drained efficiently and the soil rammed firmly, as for Ericas and other hard-wooded plants. We have frequently seen Chorozemas trained on balloon trellises; treated in this way they make a very pleasing effect with their brilliant flowers and fresh evergreen leaves. They are also effective when trained to pillars and posts, and they are admirable as loose bush plants. They should not be tied up too tightly; if the outer shoots are allowed to droop naturally they will hide the bareness of the lower part of the plant and almost cover the pots. In a cool house they will last in bloom for three months or longer. Early in June they can be plunged outdoors in a bed of ashes, pruned back a little, and treated like Azaleas. They should be housed before danger of frost, although a light frost will not hurt them at all. There are several varieties of Chorozema, including Ilicifolium, Laurenceana, Henchmanni, Cordatum and Cordatum splendens. The last-named variety is the only one we now grow; the flowers are orange and red in color, and are borne in great profusion. We consider it much the best of the family.

Streptosolen Jamesonii.—Too much cannot be said in favor of this as a winter-flowering plant. It begins to flower early in the new year, and lasts until May in good condition, and so floriferous is it that I have seen blooms on it every month in the year. It is easily propagated, and cuttings of soft wood inserted in a good bottom-heat will be nicely rooted in a month's time or less, and if potted on as required fine plants can be had in eight and ten inch pots for next winter's bloom. If grown as a half-standard, with a stem two feet long, it is more effective than when grown in regular bush form; trained in umbrella fashion it also makes a remarkably handsome plant. For compost we use good rich loam, to which is added some cow-manure or pulverized sheep-manure and a little sharp sand. The soil should be pressed moderately firm. The plants do best plunged out-of-doors in the summer and treated as Chrysanthemums are. They will need frequent waterings with liquid-manure when pot-bound. Unless extra large plants are desired, it is best to raise a fresh stock from cuttings each year, and this is a good time to insert them. In Great Britain this plant is better known as Browallia, and it is becoming increasingly popular there. The bright cinnamon-red flowers are of a color distinct from those of almost any other winter-flowering plant, and, although not of any special value for cutting, its lasting qualities merit a place for it in every greenhouse collection.

The Chestnut Weevil.

To the Editor of GARDEN AND FOREST:

Sir,—I have been interested in the growing of Chestnuts, and especially in what you have said about the Ridgley Chestnut, but I observe that a writer in the *Rural New Yorker* condemns this variety, as well as the Numbo and Paragon, because of their liability to injury from the Chestnut weevil. He states that the Japan chestnuts are not "wormy," owing to the fact that they ripen early. Now, is it true that our native varieties, or those of European blood, are more subject to attacks from the weevil than varieties of the Japan type, and does the early ripening of chestnuts exempt them from the attacks of this insect? This seems to me to be a very impor-

tant point, for a crop of chestnuts which is largely wormy is useless.

Montclair, N.J.

R. A. S.

[These points we can only answer by reference to experiments which have been made by skilled entomologists. Professor John B. Smith, of the New Jersey Agricultural College, gives an account of the weevil and its work in his report for 1893, and the trees he examined in southern New Jersey did not bear out the views of the correspondent of the *Rural New Yorker*. The fact is, that while imported trees had up to that year been comparatively free from wormy fruit, in 1893 the imported and improved varieties suffered as much as any. The Paragon, which is noted in the *Rural New Yorker* as the most affected, was here the least attacked of any, while the native as well as the Japanese varieties were largely infested. The time of ripening has certainly nothing to do with the trouble, but the time of flowering may have some significance, because the attack is made by the beetles, which appear early in the season, when the Chestnuts are still in bloom. A small hole is bored into the young bur and the eggs are deposited in the embryo nut by the long, slender beak of the beetle. The minute puncture made by the insect heals completely, so that it is impossible when the nuts are ripe to discover how the larvæ entered. These larvæ feed upon the nut and leave it any time between the middle of September and the first of November, when they go under ground for a short distance and remain until the following spring, or, perhaps, lie over until the second year, which is nature's provision for continuing the species if there should be a failure of the chestnut crop in any season. It will be seen from this that there is no period in the life of the insect when it is within reach of the poison. Where the ground is cultivated most of the larvæ are killed by the operation, especially where mineral fertilizers are applied, but Professor Smith advises those who wish to plant improved varieties of Chestnuts in land which is not tilled, to get rid of all the wild trees in the vicinity which might serve to perpetuate the species. As soon as the nuts begin to drop, every nut under the trees should be gathered at once and sent away or destroyed before the larvæ leave them. If it is found that any variety is specially attractive to the insects, trees of this sort should be scattered among those less liable to attack, in the proportion, say, of one tree to ten. The insect will be most numerous under these trees and the ground here should be kept clean so that the nuts can be seen as they fall. The crop from these trees will contain by much the greatest percentage of the larvæ in the grove, and these trees will protect to a certain extent the others. Systematic early gathering will of itself appreciably lessen the number of the weevils. Of course, wormy nuts should not be thrown on the ground, but should be burned. Nuts which cannot be marketed at once should be put into tight boxes or barrels through which the larvæ cannot make their way, and when the nuts are removed the larvæ should be destroyed by boiling water or in some other convenient way.—ED.]

Some Aspects of British Forestry.

To the Editor of GARDEN AND FOREST:

Sir,—This was the title of a paper read by Dr. Somerville, of the Durham College of Science, before the Imperial Institute, at London, December 14th.

The extension of sylviculture in this country was discussed chiefly as an agency for bringing profit to the landlord and benefit to the state. The absence of satisfactory returns from many of our existing woods was traced to excessive initial expenses, unscientific management, game, and the inferior quality, and consequently low price, of much of our home-grown timber. The poor quality of the timber was shown to be largely due to the way in which our plantations are managed, and especially to their being usually over-thinned, and too limited in extent. Reference to the Board of Trade statistics did not justify a common prediction that timber will become both scarce and dear in the near future. If, however, timber-exporting countries are cutting into their capital stock of trees, and are shipping more timber than is annually pro-

duced, a period of scarcity may arise with a suddenness of which the Board of Trade Returns need not be expected to give any indication.

The desirability of the state purchasing land suitable for forestry as a means of providing employment in rural districts was strongly insisted upon. Sylvicultural operations, and the transport of timber to the nearest sawmill or railway station, necessitate the employment of approximately one forester or other workman to fifty acres of wood, while the conversion and utilization of the timber employ an even larger amount of labor. It was pointed out that, at a low estimate, hill pastoral farms are attended to by one shepherd to a thousand acres, so that forestry can find remunerative employment for at least twenty times as many laborers as pastoral farming.

Recent Publications.

Hand-list of Trees and Shrubs grown in the Arboretum of the Royal Gardens in Kew. Number 1, Polypetalæ.

This is the first part of a catalogue of the woody plants grown in the National Herbarium at Kew, from the pen of Mr. George Nicholson, the curator of that establishment, to which the lovers and cultivators of trees have been looking forward for several years in eager expectancy, realizing that his precise knowledge and the great opportunities of an establishment like Kew would enable him to produce a work superior in scope and more accurate in detail than any of its predecessors in this particular field.

In Mr. Nicholson's list the families and genera are arranged according to the *General Plantarum* of Bentham & Hooker, and the species under each genus are arranged alphabetically. The species, therefore, are not grouped in sections or other subdivisions, and no characters make it possible for a person cultivating a plant under any given name to verify the correctness of that name by the aid of this catalogue. In some cases, however, this is made possible by a reference to published figures, although no system of the citation of figures appears to have been adopted or followed. The figure, for example, of *Magnolia hypoleuca* in this journal is quoted, while there is no reference to our figure or to any other of *Magnolia Kobus*; there is no reference made to our figure of *Acer Nikoense*, or even to the earlier one in the *Gartenflora*. Nor is there any reference to a figure of *Prunus Alleghanensis*, although it has been figured in the pages of this journal and in Sargent's *Silva of North America*, a work which is often referred to by Mr. Nicholson, although without much system, as all reference to it under the different species of American trees is often omitted. As was to have been expected, for Kew does not occupy itself with questions of priority of nomenclature, no attention is given in this work to the use of the first published name of a species; and this catalogue admirably illustrates how unsatisfactory the system is which permits an author to select or reject a name according to his individual fancy, without reference to priority of nomenclature. Usually Mr. Nicholson takes the best-known name, but not always, so that here is that inevitable mixing up again of systems which always follows the go-as-you-please plan and always results in additional confusion of names.

The valuable part of this publication, and the value of this cannot be overestimated, is the synonymy which has been carefully worked out and includes under each species, in addition to published synonyms, a list of nurserymen, and gardeners' names, which have always been the source of the greatest confusion to students of cultivated trees. The value of this feature is very much increased by an excellent index of the orders, genera, species and synonyms.

Through Glade and Mead: A Contribution to Local Natural History. By Joseph Jackson. Worcester, Massachusetts.

The Country Month by Month. Spring. By J. A. Owen and Professor C. S. Boulger. London: Bliss, Sands & Foster.

We place these two books together, not only because

they both belong to the class of what may be called outdoor books, which form so considerable a fraction of current literature on both sides of the Atlantic, but because they are identical in purpose. This purpose is to furnish to a certain extent a guide for the lovers of nature, especially for those who live in towns, which will to some extent help them when they visit the country by telling them what they may expect to find. The American book is narrower in its range than the other, and is confined chiefly to making a record of the succession of flowers, while its English companion, besides giving a current account of what is going on in the plant-world, is concerned with all sorts of wild life—birds and beasts and creeping things—which one would encounter in a rural walk.

Through Glade and Mead is a stout volume of three hundred odd pages, which, after a brief introduction, describes the salient features of the vegetation of Worcester County, Massachusetts, as they appear month after month from early March till late September. It is not possible in the compass of a hundred pages to write with much detail of many plants, but those which would naturally catch the eye are generally selected, the brief notes about them are accurate, and while there is no effort at picturesque description the work is characterized by good taste and some literary skill. The second part of the book is essentially the record of a single year, in which the dates of the appearance of the wild flowers are given for the year 1882. This is taken as a representative season. Beginning with the Skunk Cabbage, on the third of April, the record continues day by day until the second of October, when the Witch-hazel and Fringed Gentian were in flower, and includes 553 plants. The book has two appendices, one of which is a catalogue of the phænogamous and vascular cryptogamous plants of Worcester County, Massachusetts, and in addition to this flora there is a list of about two hundred trees, shrubs and evergreen flowering plants, which are growing without cultivation in the same county. Among the half-tone illustrations are good pictures of *Ledum latifolium*, *Andromeda polifolia*, the pink Azalea, *Rhodora* and *Leucothoe racemosa*. Five hundred and thirty-five copies of the book have been printed, and of these thirty-five are on large paper, numbered and signed.

This volume of *The Country Month by Month* includes the record of March, April and May, and will be followed by three others to complete the year, and it will very successfully accomplish for English readers what Mr. Jackson's book does for wanderers in Massachusetts' highways and byways. The very titles to some of the chapters which relate to plant-life, such as *By Bank and Copse*, *In the River Meads*, *On a Chalk Sub-soil*, *On Wooded Hills*, *Among Sand Hills and Firs*, *By Ruined Walls*, are alluring, and happily suggest the kind of paths which are to be followed in the various spring rambles. Nor will the reader be disappointed as he follows his guide. Indeed, although it is among Daffodils and Cowslips and Wild Hyacinths that we are invited to walk, the American reader will find these strolls quite as interesting as if they led among his native flowers, while the foreign birds and butterflies, the furry creatures which hide in the coves, and even the Old World snakes and reptiles have a certain fascination which shows that books of this kind have an interest for many who do their botanizing indoors, and who would rather read about insects than to chase them with a net. To all such closet naturalists, as well as those who prefer to observe for themselves, this book can be heartily commended as one of the very best of its useful class.

Notes.

Branches of Tangerine oranges, each bearing a dozen fruits in a setting of dark glossy foliage, now make one of the most attractive features in the fruit-stores. The best of them come from glass houses in southern New Jersey, and sell at the rate of twenty-five cents for each orange.

At the annual meeting of the Ohio Horticultural Society it was said that the commercial cultivation of the Gladiolus was carried on very extensively at Cuyahoga Falls, two growers there having produced more than a million bulbs. One man was reported as selling 300,000 bulbs in a single order for enough money to pay for a small farm.

A California paper announces that a sawmill in Fresno County has prepared a car-load of redwood blocks for shipment to Germany, where they are to be used in making lead-pencils. This is an interesting item, although the accompanying announcement that California redwood will soon entirely displace Florida cedar in this industry is perhaps premature.

The Farmers' Advocate states that persons who have failed to succeed with the Parker Earle Strawberry may have planted it in soil that is too dry. All Strawberries do best in moderately moist ground, and it may be added that weeds do the best there also; but the Parker Earle, in particular, never seems to be at its best until its roots strike permanent moisture.

In the report of the Executive Committee of the American Forestry Association, at its meeting in Washington last week, it was proposed to introduce into Congress bills to provide for obligatory courses of instruction in forestry at the agricultural colleges, as well as a course of lectures at West Point, a post-graduate course at the Department of Agriculture, and scholarships for students in forestry to be sent abroad.

Besides its great parks, London now has 198 open spaces of less than ten acres in extent, with an aggregate area of three hundred and fifty-four and a half acres. Most of these grounds have been secured for public use in comparatively recent time, and the *Gardeners' Chronicle* well says that any one who would have ventured to prophesy fifty years ago that there would have been now nearly two hundred such places for recreation and resort in the great city, would have been laughed at as a dreamer.

Dr. Hoskins says that the Old Nonesuch Apple, which is generally supposed to be of Massachusetts origin, is probably from Canada, as is indicated by its synonym Red Canada, and also by the fact that many old orchards of this variety now exist in Canada. When well-grown upon good ground the Red Canada, like the Fameuse, is a first-class commercial fruit, and it has been shipped this winter to London from Montreal in cases with paste-board divisions which make a cell for each apple, just as egg-boxes do for every egg. Shipped in this way these apples brought from \$5.00 to \$7.00 a bushel as an ornamental table fruit. Their medium and uniform size and color give them great value for this purpose. No doubt, there are other apples besides the Red Canada and the Newtown Pippin which might be shipped in this way at a profit, and our own large cities would take choice fruit so marketed at a good figure. Such apples should be uniform in appearance, size and quality, and some of the earlier varieties like Early Joe might be shipped and sold in this way, but they would need much more intelligent handling than ordinary market apples receive.

Christmas gifts supplied by florists this year consisted almost entirely of boxes of cut flowers, violets and roses being the favorites. Large, deep-colored Marie Louise violets, their long stems allowing of loose, graceful arrangement, sold for as much as five dollars a hundred. Roses cost from three dollars to eighteen dollars a dozen, an extra quality of American Beauty commanding the outside price of three dollars each. Lilacs at twenty-five cents to fifty cents a spray, tulips at one dollar a dozen, large showy heads of Poinsettia at twenty-five cents each, and stevia at fifty cents for a small bunch, were specialties of the holiday season. Carnations were plentiful and cheap; some well-cultivated specimens of William Scott, measuring two and a half inches across, brought the extreme price of two dollars a dozen. The Orchid season is now fairly begun, and cut blooms of Cattleya at nine dollars a dozen, and Cypripedium insigne at four dollars a dozen, were in good supply. Fruited plants of Ardisia crenulata and the Otaheite orange were in some demand, and specimen plants of Cyclamens and of Chinese Primroses in ornamental baskets found considerable favor. But the most beautiful and the most costly were luxuriantly flowered plants of Heath, their foliage almost hidden under the myriad of tiny bells, and a few extra early pink and white Azaleas.

The vegetable supply in New York at this season is remarkably varied, comprising the ordinary fall root-crops of our northern fields, and of Canada and Europe, the more perish-

able green crops held over in cold storage, new vegetables from the Gulf states and from the Pacific coast, and choice hot-house products from adjoining states. The principal supplies of potatoes in our markets now come from Long Island and interior sections of New York state, and from New Jersey, Maine and Michigan. Cargoes have recently arrived from Scotland, England, Germany and Belgium, and new potatoes from Bermuda are already here. The best sweet-potatoes come from Vineland, and West India yams, weighing from five to eight pounds apiece, are occasionally seen. These are cut in quantity to suit the purchaser and sell for fifteen cents a pound. Winterturnips, from New Jersey and from Canada, are abundant and cheap, while small and tender hot-house turnips cost five cents each. Carrots grown under glass may be had for twenty cents a dozen. Florida cucumbers, small and of irregular form, sell at the rate of four for twenty-five cents, the smooth and shapely hot-house product bringing twenty cents each. These have more than their appearance to account for the difference in price, since their crispness and delicate flavor is most marked. Tomatoes from the southern states and from California cost twenty-five to thirty cents a pound, the firm flesh and rich color of hot-house tomatoes making sales for them at fifty to sixty cents a pound. Small bunches of asparagus, from St. Louis, are offered at thirty-five cents each, and slender stalks of the same vegetable, from New Jersey greenhouses, are luxuries which cost as much as \$1.25 for two dozen tips. New okra, from Havana, costs ten cents a dozen, artichokes, from Louisiana, twenty-five cents each, and Florida squashes ten cents. Other vegetables from Florida are eggplants, Brussels sprouts, leeks, peas, string beans and lettuce. Chicory and escarole come from New Orleans, and radishes, spinach and kale from Norfolk. Dandelion grown in cold frames on Long Island finds ready buyers at twenty cents a quart, and the best mushrooms cost \$1.25 a pound.

The so-called Vanilla Bean is not a bean at all, as is well known, but the fruit of a climbing Orchid, *Vanilla planifolia*, the capsule or pod of which is about three-eighths of an inch in diameter and from six to ten inches long, and has a certain resemblance to the so-called Catalpa Bean. The plant in its native home, in Mexico and tropical America, climbs over trees and shrubs by means of slender rootlets sent out from the joints of the stem. It is not a true epiphyte, however, but always maintains its connection with the soil. In its wild state it climbs to a height of twenty feet, but in cultivation it is kept within bounds, so that the unripe pods are not injured when the others are gathered. A late number of *Popular Science News* contains an interesting account of the method of growing the Vanilla, in which it is stated that in Mexico the plant is propagated by cuttings and then trained over some rough-barked trellis-work in partial shade. When the plants were first introduced into the West and East Indies they grew vigorously and produced an abundance of flowers, but no pods. It was discovered that the particular moth which fertilized the flowers in Mexico was absent from its new home, and artificial pollination was resorted to, after which the plants produced abundantly. With a long splint of bamboo the lip of the flower is lifted away and the pollen is transferred from the pockets and applied to the stigma. The work is so easily done that one person can fertilize a thousand flowers in a morning. The pods require a month to reach full size and six months more to ripen. The process of curing is long and complicated, and the aroma of vanilla is said to be produced only by fermentation. In the island of Réunion, in the Indian Ocean, where the plant is grown extensively, the pods are placed in a basket and plunged for half a minute in hot water, then placed on a mat to drain and exposed between woolen blankets to the sun for six or eight days, and kept in closed boxes during the night to promote a slight fermentation. When the pods are perfectly cured they are a dark chocolate color, pliable and free from moisture. When finally prepared, the pods are tied up in bundles, packed in air-tight boxes, and when in prime condition they are covered with a frosting of needle-like crystals of vanillic acid, which, when pressed between the fingers, gives off the characteristic odor. The supply sent to New York is produced in Mexico, and is regarded as of the highest quality. The amount imported amounts to something like 150,000 pounds a year, while on our Pacific coast a portion of the supply is derived from the island of Tahiti, although the quality of this is much inferior. The supply of London comes largely from Mauritius and Seychelles, and the greater part of the vanilla imported into France comes from Réunion. Three years ago more than 500,000 pounds were imported into France from this island, which was twice the amount produced in all the rest of the world.

Parks and Park-planting.

If the word "park" in popular usage ever suggested a group of well-defined ideas, it has in these later days lost its distinctiveness, so that to one man it may mean a country fair-ground, and to another a forest, a game preserve, a field for athletic sports, a race-track, an arboretum or a military parade-ground; in fact, it is applied in a confused way to any space that is not roofed over. This is a misfortune, for, when we are discussing questions of park design or park maintenance, or inquiring what are the true functions of a park, or what should be excluded from it as destructive of its value, we must have a clear idea of what it is and what it is for. We have always used the word to indicate primarily a place where the mind and body are refreshed by rural scenery. Of course, a park will also furnish fresh air and sunshine, opportunities for bodily exercise and rest, but beyond these, and more important than these, is the refreshment of mind which comes from the influence of beautiful natural scenery. The paths and roads are not, therefore, merely places to walk in or drive over; their fundamental use is to make the scenery of the park available to persons on foot or in carriages or on horseback, so that they may find that relief and repose which natural beauty alone can bring to city-wearied senses. The value of a city park, therefore, for a city population is greater or less according as the poetic charm of its scenery is preserved and developed. It seems to be an admitted fact also that quiet, pastoral prospects have the greatest intrinsic value in enabling us to resist the wearing influence of city life and recover wasted mental energy, and it, therefore, follows that the best work is not one in which the architectural features predominate, or in which the planting aims to be highly ornamental or decorative. In a paper published during the past year at Vienna, called *Der Park*, by Franz Graf, there is an instructive discussion on the quality of landscape beauty required for a park, part of which will be found in a condensed form in the paragraphs which follow.

A park is more than mere woodland and field, but, on the other hand, it is not a garden in the narrow

sense of the word. The designers of parks invariably fall into errors of disposition and treatment when they forget this distinction. A park is not a garden, although its mere extent is not the distinctive mark of the difference between the two. There are large gardens and there are small parks, and the purpose of both is to awaken pleasurable sensations. In achieving this end, however, a garden is treated like a miniature painting. Flowers and other materials which are in themselves minutely beautiful receive loving attention in every detail. Such a garden delights us with its color, enlivens us with its perfume, cools us with its shade, but here its service ends. A park picture is drawn with a bolder hand, so that delicate work on details is dissipated and wasted. It must have something more than sensuous beauty—broader and grander features which make appeal through the imagination to the nobler faculties. Years ago our ancestors caught the right idea when, tired of the endless avenues and clipped trees of Lenôtre, they began in an imitative way to make copies of nature in their English gardens by mingling grottoes and artificial ruins and brightly colored dairy buildings with their scenery. They aimed to simulate pastoral scenery, but they overshot the mark, forgetting that a park is not a mere imitation of woodland and field any more than it is a series of formal flower-beds.

Of course, a park must be beautiful, for if it does not speak to the eye like a picture it will not appeal to the heart like a song; and if it shows no refinement of taste it falls far below the rank of what a forest, or meadow, or a vineyard may happen to be. It is a happy accident when a forest, which is treated in strict accordance with the forester's craft, chances also to be striking from a pictorial point of view, or when a meadow or vineyard, by reason of the fortunate dispositions of its hills and valleys, its foliage and its water, is beautiful as well as useful. But the first purpose of a park is to secure these results which in the woods and the meadow are happy accidents. Not only is beauty essential to a park; its whole value lies in beauty. But it must be that serene and enduring beauty which is embodied in its essential and permanent features, and not merely the transient and superficial beauty of floral embroidery. It must have dignity of expression, and not mere prettiness.

Again, although a park must be beautiful, it may be bad art to crowd it full of plants and structures simply because they are beautiful. We too often see a huddle of expensive rarities which struggle with each other to reach the light, and yet leave no reposeful spot for the eye to rest upon. This is why stretches of turf and simple wood borders are more refreshing as a spectacle to the weary than any collection of oddities which excite the eye, rather than rest it, by their glowing colors and conspicuous forms. This does not mean that a park should have no beauty of detail, but in the hand of an artist who wishes to produce an effect upon the imagination, a few beautiful things, harmoniously adjusted, mean more beauty for the whole than beautiful objects in such profusion that they cannot be grouped into any quiet and consistent picture. And since we aim at permanent beauty rather than any transient impression, this consideration alone explains why tender exotics, which seem to shudder in a cold climate, and imported novelties, which drag out a homesick life in exile, are not to be compared with native Oaks and Pines, which rejoice in the vigor of health, and grow more beautiful through years, and even through centuries.

This longevity of the noblest trees and their continued growth in dignity and beauty suggest the thought that one who creates a great park must plant for posterity. What is called planting for immediate effect is usually a makeshift, and, like other makeshifts, an expensive blunder. Light is the life of plants, and as the whole plant is condemned to death if it gets no light, any part of it which the sunbeams no longer reach is doomed. The advice to set the sapling where it will have enough light when it becomes a tree is simple, but it is constantly disregarded.

Even if we are planting to exclude some disagreeable object from sight it is better to set the trees so that they can have abundant room for their roots and light for their tops, even though during a few years we must wait patiently for the wall of foliage which is to do duty as a screen. If we plant this screen thickly the offensive object will be quickly hidden, but it will be only a short time before the lower branches give up their struggle for life, and there will remain a roof of foliage with bare trunks which hardly obstructs the view. A much more serious matter it is to destroy a good tree that is in the way. It requires firmness of purpose to destroy an object which is beautiful in itself, but it is much better to suffer a pang for such a loss than to have the life-long vexation of knowing that a tree, though noble in itself, is out of harmony and proportion with its surroundings, or that it compels some inconvenient adjustment of walks or drives, and that it will keep on doing this forever. The proper way is to plan and plant for posterity, and even if the removal of a tree leaves a wound which can only be healed in fifty years, it should be remembered that the sapling planted near it will not only fill its place, but make a complete and satisfying picture which will give unalloyed delight for centuries.

IT is not worth while to restate here our often expressed views on the subject of the distribution of seeds as it has been conducted for years by the Federal Department of Agriculture. We are glad to know that the matter was brought before the Massachusetts Horticultural Society last month, and, on the motion of the Hon. Joseph R. Leeson, seconded by Francis H. Appleton, Esq., the following resolution was unanimously adopted, and copies forwarded to the officials named in it. It is to be hoped that agricultural societies and horticultural societies which are now having their annual meetings will express their views in a similar way, and give the authorities at Washington to understand that the people of the country are tired of this abuse and intend to have it abolished :

Whereas, more than half a century ago improved varieties of seed were sent out by the official then in charge of that work at Washington, to farmers and gardeners of the country, in order that such seeds might be tested and their practical value ascertained, either over others already in use, or as to their value for introduction and cultivation,

And whereas, we recognize that the present distribution of seeds from the Department of Agriculture does not meet the original intention as herein indicated, and has grown to unreasonable dimensions (and has become a gratuitous distribution of seeds that the recipient is often unwilling to use), the cost of such distribution in 1893 having been \$160,000,

We, the members of the Massachusetts Horticultural Society, assembled by our representatives in our hall at Boston, respectfully recommend to the Congress of the United States that the present method of, and appropriation for, the distribution of seeds be abolished; and that in its stead an appropriation be made of sufficient amount (\$35,000 suggested), by which the Department of Agriculture can distribute to the experiment stations, now located in almost every state and territory, such seeds as may to the said department seem wise, and require a report upon the same from the stations, the stations to perform the required work under appropriations already provided for annually; and direct that the Secretary send a copy of these expressions to each of our Senators and Representatives and to the Secretary of the Department of Agriculture at Washington.

Black Walnut in the West.

LIKE the Catalpa, the Black Walnut can only be grown successfully in a limited portion of the plains. It reaches its greatest development in the rich bottom-lands along the Ohio and Mississippi, and its northern limit is Nicollet County, Minnesota. In the west it is found in the eastern counties of Kansas and Nebraska, but I have not heard of its being found anywhere in South Dakota. It has been extensively planted in Kansas and Nebraska, more than any hard-wood tree, except the Ash. In a moist rich soil it grows quite as rapidly as the Ash, and usually more

so. On upland soils, especially where there is a stiff sub-soil, as in most prairies, it does not succeed.

The Black Walnut is a light-demanding tree, and should always be planted far apart among good shade-makers. In this way it will grow tall and rid itself of lateral branches, making a straight clean log, free from faults. Even when planted pure, if set close, the Black Walnut cleans its trunk much better than the Catalpa. At Farlington, Kansas, there are two plats of this tree—one almost pure, and the other a mixture with Wild Cherry, which is a good shade-maker while young. In the pure plat, thirty-five measured trees averaged 3.8 inches in diameter three feet from the ground, and were twenty-four feet high, with laterals within six feet of the ground. In the mixed plat, twenty-six measured trees averaged 4.1 inches in diameter and thirty feet high. They had clean trunks to a height of fifteen or eighteen feet, with very small crowns. The trees in the pure plantation had much larger crowns, and really contained more wood in the aggregate, but since this was largely in branches it was of no value. These trees were set in 1878 as yearlings, and they were, therefore, sixteen or seventeen years old when measured.

At the home of Professor Poponoe, of the Kansas Agricultural College, Manhattan, there is a plat of about two acres of close-planted Black Walnuts which are making a strong and vigorous growth, and they are shedding their lateral branches very well. This plat is in deep soil adjacent to a never-failing spring-stream, so it has abundance of moisture. At Hutchinson, Kansas, Judge Honck planted Black Walnut seed in 1887 on half an acre of sandy loam, with water within ten to fourteen feet of the surface. Last fall about two hundred trees were found on the plat, which averaged about twenty-five feet high, and specimens eight inches in diameter three feet from the ground, were found. In going from Omaha, Nebraska, to Nebraska City I observed a very fine grove of Black Walnuts, averaging fully forty feet high. Good specimens were seen in Hastings and Red Cloud, Nebraska, but only on low deep soil. The tree is doing very well on the farm of the Nebraska State University at Lincoln.

In South Dakota, the Black Walnut is not a success. At the Agricultural College of that state a few specimens remain in mixed plats, set in 1889, but they are weak. At the Colorado Agricultural College there is a plantation of these trees of about an acre in extent, in which these trees are set twelve to eighteen feet apart both ways, resembling an orchard more than a forest-plat. The trees are in vigorous condition, but they have short trunks and large crowns. One of the best measured twenty-one feet high and five inches in diameter three feet from the ground. These trees were grown under irrigation.

Charles A. Keffer.

Notes on the Tree Flora of the Chiricahua Mountains.—I.

BY most people Arizona is thought of as the Sahara of the New World—a land of broad mesas and rugged mountains, where strange Cacti, tall Agaves and wide-spreading Yuccas flourish, while trees and shrubs with broad green leaves and shady foliage are unknown.

It is true that Arizona has unnumbered miles of broad mesas and sand-blown plains, but even here many species of shrubs, besides perennial and annual herbs, find a congenial home. Growing, as they do, where the rainfall is light, where there is little dew or other moisture, where the days are successions of bright sunshine, all the plants of the plains have small leaves, or, frequently, none, a dense pubescence, or thick epidermis. Nature, by lessening or protecting the evaporating surface, enables plants inhabiting these regions to withstand prolonged drought and the scorching heat of an almost tropical sun. The deep green of other regions here gives way to "Arizona green," a color hard to describe—a sombre gray which harmonizes well with the stretches of sand and rock-strewn hills.

Much has been written in regard to the gray vegetation of the Arizona plains. Little has been said, however, about our mountains and broad table-lands, which bear another flora, with leaves as green, flowers as bright, and shade as deep as we find in any other portion of our country.

In a two-months' trip, from Tucson to the Grand Cañon of the Colorado, and return, I have collected more than eight hundred species of Phænogamous plants. Dr. Wilcox has found between five and six hundred species in the Huachuca Mountains. On a recent trip of twenty-one days to the mountain ranges of south-eastern Arizona I collected three hundred and twenty species. The large and varied collections, made by botanists in different portions of Arizona, amply testify to the great diversity in our flora. Our plateaus and mountains give us a vegetation similar to that of more northern climates, while our southern mesas give us a peculiar and interesting one, characteristic of the planes of Mexico.

Arizona has a greater number of forest-trees than any of the other states or territories of equal area west of the Mississippi River; a greater number than Michigan or California, and nearly eighteen per cent. of the species of the United States.

During July I was one of a party who made a trip by wagon over a considerable portion of south-eastern Arizona. We rode about four hundred miles and visited the Santa Rita, Huachuca, Mule, Swisshelm, Chiricahua, Galluro and Rincon mountain ranges. Of all these ranges, the Chiricahuas are the least known, botanically. They have an interesting and diverse vegetation, and especially is this true in regard to the forest flora, since seventy per cent. of all the trees of the state are growing on these mountains.

The Chiricahua Mountains may be termed the northern prolongation of the Sierra Madre range of Sonora and Chihuahua. They occupy a large area in Cochise County, and, like the other ranges of south-eastern Arizona, extend approximately north and south. All these ranges differ considerably from each other as regards their geological formation. Owing to this, and to the fact that they are separated from each other by more or less broad strips of mesa, each is quite different from its neighboring ranges in the prominent features in its flora. A marked distinction is also noticeable in the vegetation of the mesas, when separated by mountains of considerable elevation.

Approaching the Chiricahua Mountains from the west, at the north of the Swisshelm range, we entered White River cañon, ascended this cañon to old Camp Rucker, thence over the divide to San Simon Valley, skirted the eastern border of the mountains to Fort Bowie, and ascended all the important cañons on the east side. These cañons are all thickly wooded. In many places the trees and under-brush are so dense that one can only get through after much effort. The most abundant trees are Oaks, Pines and Junipers. In the lower cañons are Cottonwood, Mesquit, Desert Willow, Black Willow, Silky Willow, Mexican Elder, Soapberry, Mulberry, Mexican Buckthorn, Ash, Box-elder, Junco, Broad-leaved Yucca, Oaks and Acacias. Farther up we find Walnut, Alder, Sycamore, Maple, Locust, Cherry, Bearberry, Hackberry, Oaks, Pines and other conifers. In the foot-hills and lower mountains are two species of Palo-verde, the narrow-leaved Yucca, two Tree Opuntias and two Acacias. On the mountain-sides, at a greater elevation, we find Juniper, Cedar, Mountain Mahogany, Arbutus, Aspen and several Oaks and Pines.

On a limestone cliff at the right, a few miles before entering White River Cañon, are growing a number of specimens of *Bumelia spinosa*, one of which measured thirty feet high and eleven inches in diameter. Here were also fine specimens of *Morus celtidifolia* and *Quercus grisea*. A trunk of the latter species measured twelve feet four inches in circumference. An interesting form of *Q. undulata*, with very undulate leaves, was found growing on these rocks. This is the only form of this very variable species, so far as I have observed, that approaches

a tree in size. Specimens were measured that were from twenty-five to thirty feet high and eight inches in diameter, and with a good clean trunk.

By the side of this cliff, along the wash from White River Cañon, were abundant specimens of *Chilopsis saligna*, *Salix nigra venulosa* and *S. longifolia*, var. The latter is a beautiful tree with rather long drooping branches and small silky leaves. A few specimens measured eighteen inches in diameter; most usually, however, this tree is much smaller. *Platanus Wrightii*, *Fraxinus velutina** (see page 15) and *Juglans rupestris* were occasionally seen, but were not so abundant as they were later. *Juglans rupestris* is more or less abundant in all the mountain ranges of south-eastern Arizona. It is most usually a small tree with white stiff branches; sometimes, however, it grows to a considerable size. Specimens were measured in the Galluro Mountains with trunks twelve feet eight inches in circumference, and long wide-spreading branches. There is a great variation in the size of the nuts of this species; sometimes they are fully an inch and a quarter in diameter, and sometimes they are not one-quarter of that size.

At the entrance of the cañon were a number of large specimens of *Juniperus pachyphloëa*, the most beautiful and symmetrical of all our Junipers. One trunk measured over thirteen feet in circumference. Growing with this Juniper were *J. occidentalis monosperma*, *Quercus Emoryi* and *Alnus oblongifolia*. Among ranchmen *Juniperus pachyphloëa* is known as Juniper, while all the shaggy-barked species are called Cedar. The Cedar is a much more durable timber, and is used extensively throughout this region in building fences and corrals.

Quercus Emoryi is the most abundant and widespread of all the Oaks of Arizona. From a mere shrub on the mountain-side it grows to great size in more favorable localities. One of these Oaks at Rosemont, on the Santa Rita Mountains, has a trunk fourteen feet nine inches in circumference, and the magnificent spread of ninety-six feet. The acorns of this species ripen as early as June, and under the name "biotes" are used for food by Mexicans and Indians. This, together with the small bunch of pubescence at the union of leaf-blade to petiole, are important characters in the identification of this species. Another Black Oak, somewhat similar, but probably a new species, was found on the mountains above Bisbee.

Tucson, Arizona.

Foreign Correspondence.

London Letter.

BEGONIA SOCOTRANA.—One cannot easily say too much in praise of this Begonia as a winter-flowering plant. It is grown in quantity at Kew, where there are now many specimens of it in flower. The finest examples of it, however, that I have ever seen are now flowering in the nursery of Messrs. F. Sander & Co., St. Albans. They are about eighteen inches high, with five or six stems, in a six-inch pot, the leaves in some cases fully ten inches in diameter, and the flowers very numerous in terminal racemes, their color a most pleasing shade of rose-pink. Is there not some mistake in the note on this plant on page 486, vol. vii., where the flowers are said to be "fully four inches across"? I have never seen any that exceeded two inches. Possibly American treatment may result in flowers twice as large as can be obtained by the best English growers. Here the tubers are started in August in a sunny moist stove, and when the plants are in vigorous growth they are placed near the glass in the sunniest possible position till they flower.

**Fraxinus velutina* is a round-topped handsome tree, thirty or forty feet in height, which ranges from the mountains of western Texas through southern New Mexico and Arizona, southern Nevada and south-eastern California. It is common in northern Mexico, and grows in Lower California. It is usually found in the neighborhood of streams, in elevated cañons, and, occasionally, on dry mesas, where the leaves are thick and leathery, and sometimes coated with a dense velvety tomentum. It is often planted for the shade of its abundant leaves in the towns of southern Arizona and northern Mexico, along the streets and on the borders of irrigating ditches.

BEGONIA REX × SOCOTRANA.—I lately saw a batch of plants in flower of this interesting hybrid in the St. Albans nurseries. They are likely to become favorites in the garden because of their combining the characters of both parents in a pleasing manner. The leaves are like those of *Begonia Rex* in form, but shorter in the petiole and more crowded on the plant, and they are prettily colored as in that species. The flowers are borne in erect sturdy racemes, which stand well above the foliage, and have much of the character of those of *B. Socotrana*, though they are paler in color. Probably, if the hybrid were again crossed with *B. Socotrana* a still better result would be obtained. But there is much to admire in the hybrid as it stands. Messrs. Sander & Co., the raisers, think very highly of it. Apparently the plants are evergreen, as in *B. Rex*, and, therefore, they may prove perpetual flowerers. Time will show. The number of crosses in which *B. Socotrana* is one of the parents far exceeds the offspring of any other species of *Begonia*.

BEGONIA RAJAH.—There are thousands of this new species of *Begonia* in the St. Albans nurseries, where it is planted on rockeries in stoves, on the sides of stages or grown in pots, and it is happy in every position. It was introduced last year by Messrs. F. Sander & Co. from Singapore. The species it most closely resembles is *Begonia gogoensis*, also a native of Malaya, but this has peltate leaves, and is not so pleasingly variegated. *B. Rajah* is dwarf, the leaves about eight inches across, obliquely cordate, and colored dark green, with large blotches of dark brown-purple-brown some would call the color. The flowers are small and whitish. It is only as a foliage-plant that this *Begonia* will find favor, and in this character it is worthy to be ranked with *B. Rex*, *B. Thwaitesii*, *B. decora* and *B. smaragdina*. Messrs. F. Sander & Co. have crossed *B. Rajah* with *B. Socotrana*, and the result is likely to be something good; indeed, no cross, so far as I know, in which the last-named species has been used, has proved other than good in a garden sense.

CALCEOARIA BURBIDGEI.—This is a handsome winter-flowering shrub of great value for the conservatory. It is grown in quantity at Kew, where there are bushes of it varying from eighteen inches to six feet in height, well branched, covered with leaves and bearing numerous large, loose, elegant racemes of bright yellow flowers. Spring-struck cuttings of it grown out-of-doors all summer and potted on as they require, much the same as Chrysanthemums, grow to a good size by autumn, and they will keep on flowering from November to May, or even longer. The plant is of hybrid origin, its parents being the large, somewhat coarse, Peruvian shrub, *Calceolaria Pavonia*, which is hardy against a wall at Kew, and *C. fuchsiae-folia*, also Peruvian, and one of the most interesting of the cultivated species from the fact that in foliage and habit it closely mimics a *Fuchsia*, and in winter it produces its pretty yellow purses very freely. Here it is planted out in a bed of good soil in June, lifted and potted in October, and kept in a cool frame until it flowers. It is hardy in Cornwall.

LOURYA CAMPANULATA.—This plant was introduced into France from Cochin China about seven years ago and was described by Baillon, who named the genus in compliment to the late curator of the Jardin des Plantes, Monsieur Loury. It is closely related to *Peliosanthes* in *Hæmodoraceæ*, resembling that genus in habit, but it has broader foliage than any of the *Peliosanthes* known to me. The flowers and fruit are also like those of *Peliosanthes*, but larger. *L. campanulata* has a root-stock like *Aspidistra*, from which spring numerous leaves eighteen inches long, the petiole six inches and the ovate lanceolate blade twelve inches by four, bright shining green, the margins conspicuously crimped; texture thin, with numerous raised parallel veins running from base to apex. The flowers are borne on a short erect raceme three inches long, and they are fleshy, bell-shaped, half an inch in diameter, pale yellow, with a black-purple disk-like centre. The fruits are three-quarters of an inch long and of a bright china-blue color. The

plant requires stove treatment. It is likely to find favor as a foliage-plant.

CYCLEA BURMANNI.—The macerated leaves of this plant when steeped in water form a jelly which is said to be equal in flavor and as a food to calf's-foot jelly. Dr. Morris recently stated in a lecture on plants which yield extraordinary substances, that a few of the leaves when crushed and placed in water would in a short time form a thick mass of transparent jelly, and that a friend of his during sickness was nourished for some time by jelly thus obtained. The plant is grown in one of the stoves at Kew, but it does not seem to possess this property here. It is a native of Ceylon and Concan. At Kew it is a slender, quick-growing climber, with peltate-oblong leaves four inches long, hairy and dull green. The flowers are small, greenish and borne in long drooping, branching panicles. It is not a plant of any ornamental value, but its jelly-producing proclivities, when grown in tropical sunshine, are interesting and might be turned to account. The genus belongs to the Menispermaceæ and is related to *Cissampelos*.

POINSETTIA.—Every one knows the value in midwinter of this plant, and every one who has a stove grows it. But while it is easy to grow plants to produce heads of crimson leaves varying from nine inches to a foot in diameter, those who can grow them to twice that size are, I opine, few in number. Locality has something to do with it, affecting the color, as it does in the case of *Calanthes*, which are paler when grown near big towns than when removed from the bad influences of smoky fog. The finest Poinsettias I have ever seen, however, arrived here a few days ago from Madeira. They formed the packing for some fine examples of the fruits of "Choco," *Sechium edule*. The rich crimson leaves (bracts) were of exceptional size, the largest being eleven inches long by three and a quarter inches wide, and the whole head was nearly two feet through. Such magnificent heads may be possible in Florida, for instance. They would make the fortune of an English market-grower if he could produce them, or of a flower-dealer if he could procure them fresh.

NATURAL v. UNNATURAL TRAINING FOR CHRYSANTHEMUMS.—Perhaps I have not made myself clear in my criticism on painfully trained specimen Chrysanthemums. I certainly never intended to discredit skill when I wrote in favor of less formal training, though "R. P." suggests as much (see p. 498, vol. vii.). In *GARDEN AND FOREST*, vol. vi., p. 456, there is a picture of what I mean by a naturally grown Chrysanthemum, and I there said that the art of the skilled gardener was needed for the production of such a specimen, though in that case it was hidden. Training should never go in the direction of distortion, unless there are very good reasons for it. We are compelled to use balloon-trellises for *Allamanda*, *Clematis*, *Bougainvillea* and *Gloriosa*, if we want to exhibit them, but not so in the case of the Chrysanthemum. The Rose is sometimes maltreated by exhibitors, who twist and bind the stems with wire in all sorts of odd ways to produce a thing like an umbrella or a fan or some such fancy. All this is in bad taste, and, therefore, is bad gardening. The same narrow view condemns as bad in habit all plants which do not form nice bushy specimens. Anything "leggy" is considered an abomination!

London.

W. Watson.

Plant Notes.

ROSA CAROLINA.—This native Swamp Rose is one of the species which flower late, with the climbing Prairie Rose and *Rosa Wichuriana*, which trails on the ground like a Dewberry. Unlike these, it has an upright habit, and reaches a height of six to seven feet, being the tallest of our wild bush Roses. It is common by waysides and woodsides, especially where the ground is moist, and its flowers, which appear in the middle of July, often last until the middle of August, since they do not open simultaneously, but follow one another in succession. The individual flowers are rather smaller than those of our other

native Roses, but they grow in corymbose clusters, and they have the special merit of possessing that typical wild-rose fragrance which everybody enjoys. A single plant will spread by underground shoots, so that in a few years it will make a large clump, and it is very useful where masses of shrubs of considerable size are wanted. We are led to speak of the Swamp Rose at this time because just now its corymbs of highly colored fruit make a very effective showing above the snow in a few of the shrub borders of Central Park, where it has found its way, perhaps, by some natural means of distribution, although it may have been planted. This fruit is bright scarlet, and it not only clings to the plant all winter, but it keeps its color and remains sound and plump until some early-flowering shrubs like the Japanese Witch Hazel are in full bloom. Altogether, it is one of our native shrubs whose value for park planting at different seasons ought to be more generally known.

but the variety *Excelsum*, or a special strain of this variety called *Harpur Crewe*, which was introduced a few years ago, seemed to give a new impulse to the cultivation of various kinds of the Leopard's Bane, which is the common name of the genus. *Doronicum Caucasicum*, which was known in the early part of this century, is itself an admirable plant for cutting, and is now quite generally cultivated. Of course, the true home of these plants is the outdoor garden, for they are perfectly hardy and among the most showy of border plants; but if they are lifted with care in autumn, potted and placed in a cool greenhouse they will be now large enough to flower, and through February and the early spring months they will bloom abundantly. These large yellow flowers are not only beautiful, but they last well when cut. The variety *Excelsum* blooms later, since it grows to a height of four or five feet, and when at its best it bears flowers three, or even four, inches across, but *D. Caucasicum* will flower much earlier in five-inch

Fig. 2.—*Fraxinus velutina* on the Chiricahua Mountains in Arizona.—See page 12.

POLYPODIUM (GONIOPHLEBIUM) SUBAURICULATUM.—Although this Fern is graceful even when young it never shows its real decorative value until it is fully grown. Its distinctive feature is the pendulous habit of its fronds, which are pinnate and bright green. When placed in a large tub and allowed to grow, these fronds, which are produced in great abundance, will hang down on every side to a length of ten or twelve feet. When placed on a tall pedestal, a specimen four or five feet through and draped to the ground with a dense curtain of green fronds makes a very striking picture. This Fern was brought from the Malayan Archipelago a great many years ago, and is one of the most graceful of the family. The bright yellow fruit-dots, like those of other Polypodiums, are sunk so deeply in the fronds that they make a little protuberance on the other side.

DORONICUM PLANTAGINEUM.—This Composite plant from southern Europe was introduced twenty-five years ago,

pots, and it rarely grows more than a foot tall. *D. Clusii* also makes a good pot-plant, although it is not so sturdy a plant for outdoor cultivation. All *Doronicums* do better in a heavy soil which is retentive of moisture.

Cultural Department.

Epigaea repens.

EPIGAEA REPENS, the Mayflower of some parts of New England, the Ground Laurel or Trailing Arbutus of various localities in eastern North America, has probably excited as much interest as any other hardy plant. Many efforts have been made to domesticate it, and few kinds of plants have so often failed to flourish under artificial conditions. In most cases where transplanting from its natural home is attempted old plants are taken up with as many roots as possible or convenient, and sometimes with earth. They are too often rudely taken from the warm shelter of woods and leaf-covered ground to some position quite different either

in exposure, temperature, humidity or character of the soil. The result is a check in growth, which is generally followed by a degeneration of the plant, which may endure for several years, but finally dies, and what appears like success for one or two years after transplanting may prove a failure at the end of five or six.

In transferring the wild plants from the woods the common mistake is to select plants which are too old. Old plants may be removed safely if an abundant mass of soil is moved with them, so that the roots are not much disturbed, and if care is taken that the new conditions do not differ too greatly from the old. Wherever possible, it is always much the best plan to collect small plants or seedlings, and grow them carefully in a well-prepared bed, or cold frame, of sand, loam and peat for a year or two before planting out permanently. They will, of course, require proper shading and watering. It may be supposed that seedlings are not always easily procured, and it is true that few seedling plants are noticed if we look for them among the heavy covering of leaves which often protect the plants. The best places to procure seedlings will be found along old paths and cart-tracks in the woods, along railroad cuts and embankments where the species abounds, and in other similar situations where the ground has been disturbed or a clearing made.

After some careful observation the little plants may be easily detected even when provided with only three or four small leaves. With proper care these will become robust specimens, and best adapted to thrive under conditions of cultivation.

In localities where the *Epigaea* is not indigenous the modes of propagation employed are division of old plants, layering or by cuttings; but these methods are often slow and unsatisfactory. It may naturally be asked, Why not procure seeds? Fruits and seeds of *Epigaea*, however, are known to few people, even among professional botanists, who are familiar with the sweet, fragrant, shy little flowers. Probably no one has ever procured seeds from a regular dealer. The dry little fruits are not likely to be noticed on the stems of the plants unless they are carefully looked for, and they may be found more plentifully in sunny open places than in more shaded ones. Doubtless, also, in some parts of the country the conditions for seed-production are much more favorable than others. Where seed can be procured it may be sown in pots, boxes or beds of well-prepared and well-pulverized soil composed of loam, peat and fine clean sand in about equal parts, and the whole well drained beneath. The seed should be sown on the surface of the soil and have a very slight covering of earth sifted over it, an amount of soil equal to the diameter of the seed, or scarcely enough to cover it, being quite sufficient. It may then be covered with fine sphagnum or dead moss, and the whole gently and thoroughly watered, and the sphagnum and surface of the soil should not be allowed to become dry afterward. If in a greenhouse or where there is warmth, the first seedlings may appear under the sphagnum in two or three weeks, and soon afterward the sphagnum must be carefully removed and a very slight sifting of additional soil may be added to the surface. Until they are well established the little plants should be shaded from the direct rays of the sun, and the more humid the atmosphere the better they will grow. As soon as they have produced one or two little leaves the plants may be thickly transplanted to pots or shallow boxes, care being taken not to let the delicate roots dry for even a moment, and as they grow and crowd they may be again transplanted and given additional room until they are large enough to be placed in beds or permanent places. Whenever practicable, it is a good plan to start the seeds in a greenhouse, sowing them soon after collecting or during the winter. After the first season the pots or boxes of little plants may be wintered in a cold frame or pit covered with leaves. Thus treated they should bloom in three or four years after the seed is sown.

One cause which contributes largely to the scarcity of seed is the fact that the *Epigaea repens* is practically diœcious—having its pollen-bearing and fruit-producing flowers on different plants—a fact which is not commonly known. An examination of the blossoms from many different plants will show that on some the styles are long and surmounted by perfect stigmas, on others the stigmas are perfect, but styles short. Both of these forms have abortive stamens, inasmuch as they either do not produce good anthers and pollen or the stamens are very rudimentary or entirely absent. On other plants will be found the male or pollen-producing flowers with perfect stamens and abundant pollen, but imperfect stigmas, incapable of being fertilized. Thus not more than half of the plants can ever bear fruit, and cross-fertilization is absolutely

necessary in order to insure seed-production, and this cross-fertilization is probably entirely dependent upon visits from a very few kinds of insects.

As found growing in its native habitat much variation in the size and color of the blossoms of *Epigaea* will always be noted. A careful examination of different specimens will show that there is a marked tendency toward larger size and whiter color among the pollen-bearing flowers, while those plants which produce perfect stigmas and fruiting organs have blossoms which are smaller, but of a richer pink or rosy color.

The flower-buds are fully developed during the summer and autumn preceding the spring blossoming, and in some localities it is not very unusual to find plants in bloom in the late autumn. The fully budded plants are sometimes taken up and potted at the end of the growing season and the blossoms forced in the greenhouse during the winter. As these plants are rarely used afterward, the practice must be regarded as a destructive one, considering the meagre results generally obtained.

Arnold Arboretum.

J. G. Jack.

Achimenes.—IV.

THREE is a group, consisting of seven varieties, which remind us of those last mentioned, as far as colors and manner of growth are concerned, as well as the flatness of the flowers. They are all of medium size and all desirable; *Carinata* is carmine, shaded salmon; *Aurora* is much like it, but darker; *Firefly*, carmine shading to purple and having an orange eye; *Purpurea multiflora* is described by its name; *Williamsi* is salmon-scarlet, with purple and orange eye and fringed petals; *Lady Littleton*, rich crimson; *Rose Queen*, rich rosy-lake, with a large orange spot. The last two are extraordinarily fine.

Of the kinds which still remain to be described, *Magnet*, *Frau Brunnow* and *Madame de Rougemont* are all precisely alike. The flowers are flat, rosy-purple, with orange-spotted throats, and the plant is very free-flowering and desirable under either name. *Alexandra* is very much like it, but bears a trifle darker flowers, and so may claim to be really distinct. *Escheriana* is small, flat, deep velvety-purple, with orange eye; *Hirsuta splendens* is another name for the same kind; *Monsieur* and *Madame Miellez* agree perfectly with each other—color, white with orange and purple eyes. Of the three *Hofgärtner*, *Mastrand*, *Neuner* and *Wendschuch*, the first is exceedingly unlike any other kind, its flowers being of medium size, trumpet-shaped, and of a beautiful lavender color, with a conspicuous white throat thickly spotted with chocolate. Altogether, this is one of the most desirable, but, unfortunately, not easily to be found, for many dealers send out under this name a reddish kind, much like *Leopard*, which has already been described. The second, *Neuner*, is flat, small, reddish purple, with yellow eye; and the third, *Wendschuch*, is the same in size and shape, but colored rose with violet shade. All three are good, the first, perhaps, the best.

Amabilis bears an exceedingly pretty trumpet-shaped flower, small, indeed, but very desirable for its lilac tint, a color very unusual in *Achimenes*. *Camille Brozzoni* and *Autumnalis* are worth having. Both are of medium size, the former flat and pink, with white throat; the latter trumpet-shaped, very deep violet, with white throat. *Pink Perfection* is a large flat flower of a pinkish-purple color. *Sir Treherne Thomas*, also large and flat, deep rose, with orange throat. *Nisida* is, to my mind, one of the very best of all *Achimenes*; it is a long-tubed, large, flat flower, lavender, shading to white at the centre, with a yellow, chocolate-dotted throat; its shape is exceedingly graceful. The true *A. hirsuta* (*Bot. Mag.*, t. 4144) and *A. pedunculata* (*Bot. Mag.*, t. 4077) are genuine species, differing horticulturally in the color of the flowers, the latter being of an orange cast where the others are rosy. Otherwise one description may serve for both: tall, strong plants, bearing in the axils of the upper leaves large, trumpet-shaped flowers on long flower-stalks, and, as the season advances, bulbillæ of small size but the same in shape as the subterranean ones. Both species should be had. *Skinneri* is the same as *A. hirsuta*. *Reticulata* is flat, of medium size, lilac-purple, with dark veins and yellow throat, very neat and pretty. *Semilosse* is tubular, deep crimson, with something of an orange cast. *Ignescens* (synonym, *heterophylla*) has almost no expanded limb, consisting of a tube only, but of an unapproachable brilliancy, a fiery orange at one end gradually changing to a blazing yellow at the other. *Chirita*, which seems identical with *Plectopoma Gibsoni* and *Scheeria Mexicana* of Van Houtte's catalogue, is the strongest grower in the genus, and will even do pretty well out-of-doors. It grows about a foot or fifteen inches

high, and its flowers are large, trumpet-shaped, and of a deep, intense violet-blue, with white throat. *Violacea semi-plena* is a poor, half-double sort, of which the less said the better. *Haageana* and *Ami Van Houtte* belong to the *Longiflora* varieties, but escaped my notice when I dealt with that group; the first is simply the typical *Longiflora*, but the other is very distinct, with its deep yellow eye contrasting with its rich deep purple surface. Dr. *Buenzod* is a flat flower, of a bluish-purple cast, not very distinct; no one need care for it. *La Belle Cracovienne* is flat, purple, with white eye; not needed. *Unique* is purple-magenta, with orange eye; superfluous. Loveliness is much like the last and deserves the same adjective.

This finishes my account, for, though I have many other kinds, they are either not now in the catalogues or not yet sufficiently described in my note-books. The lovely plant we had twenty-five years ago under the name of *Achimenes picta*, was a *Tydea*, and therefore does not belong here; the same may be said of the two *Dicyrtas*, *Candida* and *Warscewiczi*. If any reader of these notes can send me a rhizome of the *A. picta* just mentioned, I shall be glad to send in exchange any of the *Achimenes* I have named, except *Nisida* and *Ignescens*, of which my stock is exceedingly small.

Canton, Mass.

W. E. Endicott.

Notes on Lilies.

WHEN once fairly established, *Lilium auratum*, the Golden-rayed Lily, is an easy plant to manage, and I believe it may be made as permanent as any of the Lilies. It often happens, however, that it flowers but once after the bulb is set. This is as much owing to the manner of planting as to anything; if the bulb is perfectly free from rot, the soil well spaded and enriched to a good depth beneath it, and nothing but sand or a light loam is allowed to come in contact with it, a good root-growth at its base is ordinarily assured. When this is the case the plant will not only bloom the second year, but will produce much larger flowers, and the bulb itself will increase in size. I have seen bulbs which produced good stalks and flowers whose root-growth beneath the bulb was almost nothing. Above the bulb was a dense growth of roots from the surface of the ground to the bulb, and these sustained the stalk and flowers. The bulb, however, degenerated instead of improving, and would not bloom the second year. Not only should the soil be enriched beneath the bulbs, but the surface should also be well fertilized, in order to feed the many roots along the stem above the bulb. It is surprising what an enormous root-growth one of these large healthy bulbs will make if properly set; and, compared with the ordinary size, it is astonishing how large the plant may be made to grow with extra care.

Lilium Philadelphicum, the Wild Orange-red Lily, though usually found in very poor soil, responds to high fertilization as quickly as any species. It requires, however, a light well-drained soil, and it seems useless to attempt to grow it in clay. When a light sand or loam is used it is as easy to grow as *L. Canadense*. It is a very striking plant when it attains its maximum size and is in full flower. Its height, under the most favorable conditions, is more than double that of the ordinary wild plant, and the number of flowers is greatly increased.

The new and rare *Lilium Grayi* of the southern Allegheny Mountains is, I believe, destined to become a popular species, if it ever becomes common enough to be sold at reasonable rates. The bulbs more than double in size in the first season of cultivation. The best collected bulbs I have yet been able to get were poor compared with those that had been cultivated for one season. *L. Grayi* is a fine Lily, and grows two or three feet high, with two or more dark orange-red flowers, spotted inside. In shape and color the flower is not very unlike *L. Bolanderi*, of Oregon, but it is larger; the plant also is much larger and is more easily grown. In size and shape a good bulb of this species is very like that of an ordinary Meadow Lily. It may be propagated from scales like the Meadow Lily.

Few Lilies may be grown with as little care in the preparation of soil and other particulars as *Lilium Wallacei*. It is not a tall species, seldom growing more than fifteen inches high, but its erect salmon-colored flowers, three or four inches across, are very showy. It seems to be one of the reliable hardy kinds which every one should try. It increases fast, and two or three bulbs soon form a mass of bulbs and stems. Although it is easy to grow, it responds to extra treatment, and a mulch of straw-manure in autumn is a good stimulant for it. It likes a little heavier soil than some other species, and when

set in sand is benefited by a mixture of clay and leaf-mold or peat under the bulbs. It transplants well in spring or autumn. Last spring I had twenty-five good bulbs, and the flower-buds were well formed. The place in which they were planted was not sufficiently well drained, so that it was necessary to transplant them. They did not suffer in the least from this treatment, but grew much faster, and were the best plants of *L. Wallacei* in my collection.

Laelia autumnalis.

MEXICAN ORCHIDS take kindly to our system of cultivation under glass. They flower freely, make satisfactory progress each year, and in many instances the bulbs made here are superior to those made in their native land. There are but few exceptions to this rule, *Cattleya citrina* being, perhaps, the most noticeable. *Laelia autumnalis* is one of our best autumn-flowering Orchids, and, among *Laelias*, ranks next in importance to the varieties of *L. anceps*. A few years ago a white-flowered form of *L. autumnalis* was unknown, but there is now a fine plant in the collection of C. G. Roebling, Esq., of Trenton, New Jersey, and as it appeared the other day it is worth going a long distance to see. There were two spikes bearing six flowers each, their color pure white, with no tinge of pink. This collection is especially rich in white forms of *Cattleyas* and *Laelias*, and no opportunity is lost to make it as complete as possible. Perhaps the best of the colored forms of *Laelia autumnalis* is the one known as *L. atrorubens*. This is a rich carmine, and fades less than the commoner kinds. They are all worth growing, since they last so long on the plant, although when cut the flowers of *L. autumnalis* and *L. anceps* keep poorly, presumably on account of the wiry nature of their stems. When left on the plant they may be enjoyed for three or four weeks.

Laelia Arnoldiana seems to be little more than a well-marked form, probably geographical, of *L. autumnalis*, which it closely resembles. It flowers at the same time of year. All of these *Laelias* may be had in bloom at Christmas-time without any trouble.

Mexican *Laelias* like plenty of light in the growing-season; a very light coat of white lead, thinned with kerosene, and, if desired, tinted with chrome-green, is a good shading medium, as it comes off readily in the fall. A green-tinted shade is not so conspicuous in the landscape as a white one. If shade has to be provided early in the year, it is better to thin the white lead with turpentine, as this dries rapidly, and is not liable to be washed off by rain or evaporated moisture, as may happen when kerosene is used. In summer, when the kerosene dries quickly, this objection to its use does not hold.

We use no material but Fern-root for these Mexican Orchids. The resting period in winter, and the consequent drying out of the material, soon kills moss, if it is used, and makes it unfit for the roots, but if Fern-root alone is used, water can be abundantly applied all through the growing season, and with an airy house there is no trouble in growing these Orchids and in producing bulbs as large as are made in Mexico.

South Lancaster, Mass.

Luculia gratissima.—This is one of the oldest of garden-plants, but, like many other beautiful greenhouse subjects, it has been pushed to one side lately for some reason, possibly owing to the rage for Orchids. It is the first exotic plant whose name I mastered as a child, and I well remember how a specimen planted out in a warm house by my father used to fill the house with the fragrance of its abundant flowers at Christmastime. For a few weeks past the *Luculia* has been a conspicuously beautiful object here, and it is only repeating what it has done for several successive years. A correspondent tells me how beautiful it is in the gardens of Mr. Sturtevant, in California, where it thrives in the open air. It would, no doubt, prove a fine subject for outdoor planting in the climate of Florida, wherever the Poinsettias live outdoors, as they do in the Orange belt. It will endure any amount of sun-heat, and will thrive here in the cool house in winter, so that *Luculia* will flourish wherever the Orange grows well. It is a handsome plant for the greenhouse, and can be cut back after flowering every year so as to keep it in reasonable shape and bounds. *L. gratissima* is hard to propagate, or at least bears that reputation, but if cuttings are put in after the flowers have been cut off, and rooted in a cool house, success is fairly certain. In a warm propagating-house red spider is too likely to attack the plants.

Euphorbia jacquiniæflora is the older and best-known name for a fine old winter-flowering plant now known as *E. fulgens*.

We always count on a fine lot of wreaths of scarlet bracts at this period when choice flowers are scarce. Pot-culture is not good treatment for this plant usually; it is far better to plant it out in a house similar to that in which Roses are grown, it will stand all the sun in summer, and make fine growth that may be trained up under the rafters, or at the ends of the house where it will not interfere with the other occupants.

Bougainvillea glabra is now in full bloom, giving us our winter crop of flowers that are really more useful than those that come in summer, and better colored, too, for in summer the house has to be shaded, and this lessens the intensity of the color of the bright pink bracts. To get the *Bougainvillea* in bloom at this season it is necessary to plant it out in a warm house that is kept at a minimum of sixty-five degrees at night in winter, and when this crop of bloom is cut off, the plant is cut back and allowed to grow again. After flowering it is once more cut back in late August, so that we get two crops of flowers every year. It is a mistake, when planting *Bougainvillea* out, to give it unlimited root-room, the growth will be so luxuriant that it will not flower well, but if the roots are restricted to a square yard of space, with soil two feet deep, the results will be very satisfactory. Now that we have so fine a variety of this old plant as that sent out recently by Sander, it is reasonable to suppose that we shall see more of the *Bougainvilleas* in gardens. They are beautiful greenhouse climbers, doing equally well in a cool or a warm house, the long sprays of bright pink flowers being admirably adapted for table-decoration, and they show well under artificial light.

Boston, Mass.

Plantsman.

Chrysanthemums, Old and New.—Before the Chrysanthemum season passes entirely out of memory it may be worth while to say a word about the yearly accounts of the great improvements made in this flower. Now, it is true that the new flowers which are so much in vogue are large and of great substance, but in all that makes for beauty few of them have any greater value than those which were grown ten years ago. There have been occasional gains in new forms since that time, as, for example, Mrs. Alpheus Hardy and Lillian Bird, and there have been some additions which were noteworthy for other features, as, for example, H. W. Lincoln, Vivian Morel and a few others, but these are exceptional gains. No effort has been made to secure varieties which were better for cultivation in the open air, so that amateurs for the present may as well confine themselves to old varieties, and especially to those with thinner petals, as they are less liable to be injured by frost. Years ago I cultivated the old Peter the Great, a thin-petaled variety, which would endure a surprising degree of cold.

Correspondence.

A Winter Water-garden.

To the Editor of GARDEN AND FOREST:

Sir,—One of the most quaint and interesting remnants of an old Dutch homestead in Flatbush, now an incorporated part of the city of Brooklyn, is the roomy old mansion built to replace one burned by the American soldiers to deprive the British of its shelter during the Revolutionary War. The white shingled sides are divided by many windows, with their original small panes, and no fewer than seven doors open out into the garden and grounds. This has for many years been the residence of Mr. John McElvery, who is well known for his success with aquatic plants, as well as in other branches of horticulture. A lot, not above a half-acre in extent, provides for trim lawn spaces, two open Water-lily tanks, and masses of the best sorts of garden-flowers from March to November, and this succession of flowers is accomplished by an amateur grower, without any gardener and without any structure that can be dignified by the name of a greenhouse. The human and historic interest of this delightful home-garden is increased by a corner set apart for colonies of bees and cotes of homing pigeons, and by an old-time well, recently covered over, built, as a stone near its curb records, in 1796, and which, until connection was made with the town supply five years ago, furnished all the water used on the place.

By an ingenious arrangement, the result of experiments during the past five years, even winter is converted into a season of flowers, and on one of the coldest days last week I found growing in what looked like a span-roofed cold frame, abundant flowers and foliage of four varieties of tender Water-lilies. In this long, low, glass-covered tank, in its setting of snow frozen so hard that one could walk on its surface, were

some thirty open flowers, pink, blue and white, and many promising buds. A plant of *Nymphaea Zanzibarensis azurea* carried twelve flowers and buds, and several flowers of *N. dentata*, each measured nine inches across their snowy petals. Besides *N. dentata* there were in flower *N. Devoniensis*, *N. Zanzibarensis* and *N. Lotus*, with its smaller and fuller flowers. The leaves of the plants were healthy, and compared not unfavorably with summer foliage, the larger ones being fourteen inches across; new ones continuously appear, so that some have to be picked off from time to time to prevent their decay from overlapping.

Mr. McElvery began with the idea of using the tanks for a winter storage-house for tender and half-hardy varieties of Water-lilies, but successive improvements have developed this flowering winter-garden. The excavation, which measures thirty-two feet in length and six feet in width, was dug three feet deep and the sides and bottom lined with bricks set in Portland cement. This has since been found to be too deep, and a foot and a half of ordinary soil has been filled in; the plants, which are all in pots, are thus brought nearer the surface. The side walls are level with the surface of the ground, above which is a twelve-inch plank an inch and a quarter thick; the water is kept about two inches below the top of the wall. The ridge-pole along the centre supports sashes on either side; these are about fourteen inches above the water at their lower end, with a pitch of eight inches from the ridge-pole. The sashes can be lifted entirely, or, for ventilation, may be pushed down from the top. In very cold weather they are opened two or three inches during the middle of each day, while in less rigorous weather more fresh air is allowed. It is practicable in almost any winter weather to lift a sash for a short time to allow a better view of the flowers, since there is a sufficient volume of warm, steaming air inside to prevent a sudden chill. In very cold weather this rising mist settles in the crevices and joints, and, being frozen, hermetically seals the frame, so that, after a severe night, the sashes cannot be lifted until the sun has thawed them out.

The heating of the tanks is arranged for at one end of the frame, where a small pit, eight feet deep and reached by a perpendicular ladder, contains standing space and a boiler-room three and a half by four feet. The stove, as the arrangements throughout, has developed under Mr. McElvery's hands, and beginning with a small, discarded heater which had made the journey from Scotland years before, a self-feeding box was arranged for coal above the fire-cylinder, which is encircled with a boiler having a capacity of but three gallons. An inch and a half supply-pipe of wrought iron enters the bottom of the boiler, the connection of the hot-water pipe being made at the top of the boiler, a foot above.

The tank was at first divided into four equal sections, each eight feet long, but the middle partition has been taken out, so that there is now a centre section sixteen feet long, with a section eight feet long at each end. A larger surface was found to be desirable to allow more room for the leaves to spread, and Mr. McElvery advises a width of nine feet instead of six, for the same reason, and this wider stretch would still make it easy to reach half-way across to remove the old leaves. The central section and the smaller one nearest the furnace are heated by hot-water pipes; the small section farthest removed has no piping and is used only for wintering half-hardy aquatics and for seedlings. The glass partition above the dividing wall between the first and middle sections is omitted between the middle and end sections, and considerable heat reaches the storage-tank in this way. The first section is heated by a return-pipe which extends through the middle of it, four inches from the surface of the water. For the middle tank another return-pipe is carried along the bottom of the first tank at the side, where it is covered with asbestos and sealed in cement to prevent escape of the heat until it passes into the large section, through which it extends and returns to the boiler. An expansion stand-pipe is provided in each section. Besides these pipes, which have the necessary check cocks, a half-inch pipe is arranged to carry fresh water. With but little care the water is easily kept at a temperature of seventy-five to eighty degrees, which is the best suited to the health of the plants. Snails are kept in check by raising the temperature to ninety degrees once a week, and afterward turning on a spray of cold water, which in winter averages sixty degrees, serving also to freshen the tanks. A chance rise of temperature to 110 degrees did not injure the plants, while an accidental increase to 130 degrees once killed *N. Zanzibarensis* and the hardier varieties.

In the cool section, at the remote end of the tank, are stored Water Hyacinths and some plants of *Nymphaea Mexicana*, which have not proved entirely hardy and have been lost in the open ponds. Here the foliage keeps a bright green all the

winter. *Nymphaea pygmaea*, the yellow *N. helveola* and some seedlings of the Egyptian Lotus are also wintered in this section. The latter, which usually flowers in two years, have not yet bloomed here, though they are past three years old.

During the recent cold wave the plants escaped any injury in the sudden drop from thirty degrees to six degrees, and after two weeks of freezing weather they continue to flower luxuriantly. The sashes are, of course, very close to the flowers, and the snow, after melting and freezing fast, cannot well be removed without damage to the glass. Blankets were thrown over the snowfall of a fortnight ago, and it thawed off in two or three days, with no injury even to the buds. The tops of the pots are from two to six inches below the surface of the water, the older plants requiring sufficient depth of water to float the leaves. The depth of water is not considered a material detail, and while Mr. McElvery uses pots, he prefers pans for young plants. The soil in the pots is one-half good garden-soil and one-half cow-manure. Better success is had with fresh manure, although it causes a green scum, and is likely to ferment and throw the bulbs out of the pots. The scum is removed by overflow a few times at the beginning of the season, when there is no further trouble. This is done by laying a hose in the water, and thus gently floating the surface, rather than playing a hose into the pond from above, with the effect of dissipating the scum through the water.

Behind the ladder which leads into the furnace-pit, an excavation of thirty-six cubic feet gives room for a ton of coal, and at the side of the furnace-pit a door opens into a glass-covered cold pit, seven by ten feet. Here many garden-plants are successfully wintered, and, among others, Amaryllis, Imantophyllums and Azaleas come into flower. In a large collection of the best Crinums, tender varieties, as *C. Kirkii*, *C. ornatum* and *C. amabile*, do especially well, and flower profusely in an average temperature of fifty degrees. The entrance to the boiler-pit is covered with a trap-door, and an extra, heavier door is provided for more complete exclusion of cold and rain. The only other provision against weather is a padding of straw along the sides of the tanks, which is boxed in with boards.

The development of this successful winter pond has come about through intelligent practical experiments, and no less intelligent and affectionate interest in the plants themselves. The expense of changes in piping, etc., has added considerably to the cost of these frames as they now stand, but Mr. McElvery estimates that with the digging, bricklaying and cementing done by home-labor, the entire cost for frames of similar size need not exceed \$125.00. This includes the walls, piping, sash and boiler. A ton of nut-coal lasts over two months, and a water-garden on the south or south-west side of a greenhouse, with connecting pipes from the greenhouse, could be run at even less cost for fuel than is this separate plant.

Altogether, this is a most instructive experiment, and it shows how much can be done with a small expenditure of money by one who really loves flowers. Mr. McElvery has proved that it is just as easy to have choice Water-lilies in the winter-time as any other flowers, and that they can be grown quite as cheaply as any of the ordinary inhabitants of the greenhouse. Indeed, they are grown at even less outlay, after the first cost of the pond, than, perhaps, any other class of flowering plants, and they practically take care of themselves, the main work connected with their cultivation being to get rid of the surplus plants. Mr. McElvery would doubtless give further details relating to the arrangement of his tanks and cultural directions to any one interested in the subject.

Recent Publications.

Timber-trees, Native and Foreign. By the late Thomas Laslett. Second edition, completely revised, with numerous additions and illustrations, by H. Marshall Ward, Professor of Botany in the Royal Indian Engineering College, Cooper's Hall. Macmillan & Co., London and New York. 1894.

A number of trees in North America are popularly called Pitch Pines, a common appellation in this country for all the species with two or three leaves in a sheath, thick ridged bark and coarse resinous wood. The Pitch Pine of New England and of the middle states on the Atlantic seaboard is *Pinus rigida*, a common species at the north, but in the south only found on some of the foot-hills of the

Appalachian Mountains, reaching the extreme southern limits of its range in northern Georgia. The wood of this tree, except for fuel, has little value, although at the time of the first settlement of the mountainous parts of the middle states, and before railroads made the transportation of timber from one part of the country to another possible, the trunks were sometimes hewn into sills and beams for houses. In the first edition of Mr. Laslett's work we are told that this tree is found spread over a wide tract of country between the Penobscot and Mississippi rivers and that the wood is chiefly employed in shipbuilding. The wood is carefully described, and tables showing the results of experiments undertaken to test its strength are published. We are told, too, that the southern states produce the best spars for masts, timber and plank, and that these are shipped to England from the ports of Savannah, Darien and Pensacola. In the present edition this chapter is reprinted without change, except that the editor tells us that *Pinus rigida* must be distinguished from the very different *Pinus australis*, called Pitch Pine in the southern states.

It is impossible to know, of course, whether the tables relate to experiments made on the wood of *Pinus rigida* or of *Pinus australis*; presumably, however, they relate to the last species, for the wood of *Pinus rigida* probably rarely reaches England, all the American pitch pine used in Europe being the wood of *Pinus palustris*, of which *Pinus australis* is a synonym. This confusion in the minds of Europeans with regard to these two trees, one the most valuable of all Pine-trees, and the other one of the least valuable, is of ancient date, and year after year European silviculturists import quantities of seeds of *Pinus rigida* in the belief that they are to produce the trees that yield the American pitch pine of commerce. Errors of this kind die hard, but it was not to have been expected that such a palpable one which has been exposed over and over again in standard American publications would be perpetuated in a work of such scientific pretensions as this.

Timber and Timber-trees deals primarily with timbers of the British colonies, although this hardly seems the reason for dismissing *Pinus palustris*, one of the most valuable timber-trees of the world, with half a dozen lines; but this short paragraph enables the editor to insist, after having mixed up this species with *Pinus rigida*, that "it must be distinguished from the northern *Pinus rigida*, etc., which is exported under the same name." Nor does it seem possible that any work upon timbers could have been written in these days without some allusion to the California Redwood, or to the Port Orford Cedar of Oregon, or to those most valuable Japanese woods produced by two species of *Chamæcypris* and by *Zelkowa Keaki*. It seems strange, with our ideas of botanical geography, to read of *Picea Engelmanni* as an inhabitant of Canada and the northern states, although this Rocky Mountain species does reach in a comparatively depauperate form some of the mountain ranges of British Columbia.

Americans who have seen the great Live Oaks of the south Atlantic coast region, with trunks six to eight feet in diameter and immense limbs shooting out for a distance of fifty or sixty feet, will be surprised to find this tree described in a scientific work as a tree "of very moderate dimensions when compared with the White Oak, its usual height being only about thirty-five to forty-five feet, with a diameter of twelve to eighteen inches." No specimens of this wood could be obtained in England large enough for testing, but Mr. Laslett judged from its appearance that it was stronger than that of any other known Oak, although in reality the wood of eight other species of North American Oaks is stronger. This has already been published more than once; but, curiously enough, Professor Ward appears to have overlooked the fact that the Government of the United States instituted fifteen years ago a comprehensive series of tests to determine the value of the wood of every North American tree, and that the results of these tests were printed in elaborate tables in the ninth volume

of the Final Reports of the Tenth Census of the United States.

The value of *Timber and Timber-trees*, in its second edition, is greatly enhanced by Professor Ward's introduction, in which he discusses the nature of timber, with the different ways of looking at it by different classes of individuals, such as timber merchants, engineers and builders, carpenters, chemists, physicists, botanists, foresters, etc., and he has recast and brought down to date the chapters on the growth and structure of trees, on their diseases, and on the seasoning and preservation of timbers; and it is to be regretted that that portion of the work devoted to the specific account of the different timber-trees of the world and their products has not been also brought up to the existing state of our knowledge of the subject.

Notes.

The people of Baltimore have decided by vote to invest a million dollars in another park. The ground selected is well known as Clifton, the splendid estate of the late Johns Hopkins, and one of the many beautiful country homes that lie on the outskirts of the city. The money for this park has been accumulating for twenty-five years from annual taxes on the gross revenue of the street-railway companies.

A new Peach called the Triumph, and originated in Georgia by Mr. J. D. Husted, is a freestone variety, which ripens as early as the Alexander and other clingstones. Charles Downing said that a freestone peach as large, early, handsome and as good in quality as the Alexander would be worth millions of dollars. Mr. J. H. Hale, who usually speaks with caution, states his belief that the Triumph has all these good qualities.

The report of the legislative committee which was appointed to investigate the charges of fraud in the administration of the Minnesota Pine-lands seems to have discovered a great many abuses, and it is believed that the state will be able to collect many thousands of dollars as the result of their labors. It is plain that immense amounts of timber have been dishonestly taken and sold, and it is charged that the Hinckley forest-fires, which destroyed more than five hundred lives and millions of dollars' worth of timber, were set by stumpage-thieves to cover up their stealings of timber in the state lands.

The Dutchess County Horticultural Society was organized at Poughkeepsie on the second of January, with the following officers: President, James Blair, gardener to Ogden Mills; Vice-President, M. J. Lynch, Poughkeepsie; Treasurer, James Sloan, Poughkeepsie; Secretary, Wallace Gomersell, gardener to Winthrop Sargent, Fishkill-on-Hudson. It is creditable to the gardeners and florists of that section that they have formed such a society, and it is to be hoped that they will have abundant coöperation and sympathy, especially from the landed proprietors in this favored region. There ought to be many true friends of horticulture in Dutchess County outside of the ranks of those who have made it the business of their lives.

In a bulletin recently published by Professor E. W. Hilgard, of the University of California, it is stated that the Australian Salt Bush, *Atriplex semibaccatum*, can be grown as successfully on the alkali lands of the San Joaquin valley and elsewhere in that state as a forage-plant. Where the percentage of alkali in the soil is very high this can be materially reduced by planting the Salt Bush and removing each cutting from the land. The yield is double that of either Oats, Barley or Wheat hay and as much as that of Alfalfa, while its composition outside of the Ash makes it an excellent stock-food, and it seems to be readily eaten by them. It is not definitely known whether the large amount of saline ingredients would be harmless to milch cows. Certainly they would not need any salt, and if no purgative effects follow the eating of the plant no other disadvantages need be apprehended.

The *Bushberg Catalogue*, which we have again received, is something more than a mere catalogue. Its full description of the various kinds of Grapes cultivated in this country, makes it very useful and convenient for reference, but the chapters which precede this list also have a genuine and permanent value. The notes on the classification of true Grapevines by Dr. George Engelmann, the viticultural observations on our native species by T. V. Munson, the chapter on fungous diseases of the Grape and their treatment by Professor B. T. Gallopay, the account of insects injurious to the vine, as well as

those which are beneficial, by Professor C. V. Riley—all these are the work of recognized experts, and besides these there are practical notes on climate, soil, planting, cultivating, grafting, training, packing, wine-making, etc., which are instructive and helpful, so that the book can be commended as a useful one to all those who grow grapes for market or for home use. It is issued by Bush & Son & Meissner, Bushberg, Missouri, at the price of fifty cents.

Now that a growing interest is manifest in the subject of nut-culture, Dr. Hoskins observes that too little is said about the Butternut, especially for growing in the cold north. In quality the meat of the butternut is rich, and, to some people, it is more agreeable than that of the English walnut, but its rough outside is not attractive and its shell is hard. We never heard of any attempt at growing select varieties, although the wild trees differ very much in the quality of their nuts. Perhaps some varieties of value could be secured by crossing our native Butternuts with the foreign species, and a seedling Butternut will bear when it is quite young. Dr. Hoskins planted a few butternuts in rows sixteen years ago, and the trees from this seed have been bearing good nuts for several years, and he finds that the best varieties can readily be grafted on trees bearing inferior nuts. The whole business is simple, and Dr. Hoskins has proved that growing butternuts will pay, at least as well as growing apples.

In an excellent paper on the Ventilation of Glass Houses, read before the Society of Minnesota Florists, Mr. Lewis Wilde argued against the common error of considering ventilation nothing more than an easy means of regulating temperature. He explains how the change of the exhausted air of the houses for the purer outside air supplies carbonic acid gas, to be taken up by the leaves of plants, and especially how ventilation regulates the moisture in the air which indirectly influences the growing process of plants. When the air in a house is completely saturated with moisture no transpiration from the leaves can take place, and, therefore, no water containing diluted food is taken up by the roots, and consequently the plants will grow feeble or die. This is the danger in cool weather when the houses have been watered and syringed without ventilation. When the ventilators are open, the moisture-laden air is replaced by the drier air from without, the leaves at once begin to evaporate moisture and root-action and nutrition goes on in a normal way. The fact that as the air grows warmer it is capable of taking up more vapor furnishes a probable reason for the check of Roses under glass in the autumn and spring when there is no fire-heat. During the day the temperature will rise high and it will sink correspondingly during the night and early morning. In the daytime a large quantity of vapor is taken up, enough to completely saturate the air when it cools down at night, and the Rose-leaves, not being able to evaporate any moisture, will suffer a check as soon as the rays of sun fall on them. In order to prevent this, fresh air should be given during the night with fire-heat when the temperature does not fall below sixty degrees.

Florida oranges, which have been wholesaling at about \$2.00 a box, have advanced to \$4.00 and \$5.00, with a prospect of a still further advance for good fruit, if any can be secured. The cold wave which visited Florida in the last days of December was the most disastrous known in the history of that state. Ice formed an inch thick as far south as Lake Worth, and in many other sheltered places where Orange-groves had heretofore been safe, the fruit was frozen solid on the trees. The loss to the fruit-growers, as well as the merchants, transportation companies, the packers and all those in any way connected with what promised to be a most profitable season, has been almost as serious as if the state had been swept over by fire. Owing to the drought of last summer the Orange-trees bloomed late in the fall, and there was promise of a large crop of late fruit. Of course, this is all destroyed, and the fruit-buds for next year's bloom are probably ruined. Many young orchards are killed, and many of the old trees will be cut back seriously. The salable oranges now arriving in this city are those which had been picked and were in packing-houses before the cold wave. Some oranges which were caught by the frost in transit bring little or nothing. Grape-fruit now sells at \$6.00 a box at wholesale, and the price is steadily advancing. To meet the deficiency caused by the disaster in Florida, large orders have been cabled for Messina and Palermo oranges, and Sicilian fruit now here is commanding high prices. Oranges are already selling in the groves in California at an advance of \$1.50 a box. Apples and other fruit have not yet felt the effects of the scarcity of oranges, but all kinds of winter fruit will probably be dearer as they are called upon to supply the deficiency.

A Novel School of Horticulture.

DURING its session of 1894, the Legislature of the State of New York passed what was known as the Experiment Station Extension Bill, which, among other provisions, appropriated \$8,000 to be expended in the western counties of New York; under the direction of Cornell University, for the benefit of horticulture. The fund was to be used in conducting experiments and investigations, in studying plant-diseases and the most profitable ways of fertilizing vineyards, fruit-orchards and gardens, and in publishing the results of such investigations and in disseminating horticultural knowledge by means of lectures and otherwise. Early in December we received a conspectus of a School of Horticulture, to be held in Chautauqua County on the last week of the year during four days and to be conducted by Professor L. H. Bailey, in accordance with the provisions of the act we have quoted above.

The programme, as announced, looked attractive. It seemed that this school of horticulture was the very natural and satisfactory development of the Farmers' Institutes which are held in various parts of the country now, and many of which have become specialized so as to take up a single branch of agriculture like dairy husbandry, fruit-culture or the like. The most noteworthy fact brought out in the announcement was, that although this institute was to be held in one of the famous grape-growing regions of the state, small promise of instruction was offered in what might be called the practical and every-day working details of horticulture or viticulture. Only one afternoon was to be occupied in any matter of manual skill, and this time, devoted to general nursery practice, was given largely to a discussion of principles rather than of methods. The course was confined almost exclusively to the fundamental principles of horticultural science. Thus, the subject of the first half-day's session was How Plants Live and Grow, accompanied by demonstrations with the microscope by Professor Rowlee. Another half-day's topic was a brief on the Evolution of Plants, with the Origin of Varieties. One session was devoted to the Geological History of Soils, with stereopticon views; another to the Chemistry of the Grape and of the Soil; another to the theory of tillage and the productivity of land; another to the subject of

Fungi, with stereopticon views. This tendency toward strict science is something like an innovation on the ordinary Farmers' Institute work, but, plainly, it was the proper course to pursue, and it promised to furnish the students with what was really the most practical kind of information which could be given them within the period named. Another interesting point was that each session was to begin with lessons in observation. At one session the subject to be studied was twigs, at another fruit-buds, and again seeds, leaves, flowers, fruits, and last of all, the apple. This also appeared to us to be a feature full of pleasing promise, and we have, therefore, made some inquiries of persons who attended the school, both in the capacity of instructors and as students, to ascertain whether the venture had proved satisfactory.

From the letters received we learn that sixty persons registered as students, and nearly all of them answered to the roll-call at every session. These students were all practical horticulturists, most of them grape-growers in the famous Chautauqua valley; among them were two or three physicians, a clergyman and others who had adopted the pursuit of horticulture either as a business or a diversion. The interest increased as the sessions went on, and nearly all the students took notes upon the lectures and passed satisfactory examinations on them afterward. Perhaps this is the first school or institute of the kind which was ever held in this country, and it seems to have been unqualifiedly successful. The observation-lessons were remarkably stimulating, and it was surprising to see what interest even the elderly men took in the simplest objects. When twigs of various kinds were passed about the first day, ten minutes for observation were allowed, and then the various members of the class were asked what they had seen. As the subject of phyllotaxy, or the arrangement of buds on the stem, had not been studied by many of them, the class became almost excited as the mathematical ratios developed by the arrangement were brought out. This experience was repeated at every session, for there was not a single observation-lesson in which the discovery of some equally striking law or truth was not made by carefully studying the most familiar objects which had been before their eyes every day of their lives. Perhaps the most interesting lesson of all was the very last one, when, after the flowers had been studied, the structure of the apple was taken up. As the meaning of the various parts of the fruit was revealed, and their relations to the parts of the flowers became evident, the wonder of many members of the class at what was novel information to them was very manifest.

Of course, it is not to be expected that accomplished horticulturists will be graduated from a school like this after four days of instruction, but whenever a man learns new fundamental scientific truth he becomes to this extent more intelligent in the practice which rests upon this truth. Certainly a man will cultivate his land more efficiently after he has listened to the explanation of Professor Roberts, who showed in what way tillage promoted capillarity of the soil and how it brought fertility to the plant, set free mineral nutrients, hastened nitrification, presented new surfaces to rootlets, conserved moisture, and did much more besides. With some knowledge of these fundamental principles any horticulturist would be better able to judge when to cultivate and how to cultivate. It is not to be assumed that Professor Caldwell in his lectures on the chemistry of the soil and of the grape made expert analysts of any of the Chautauquans, or that in a single afternoon Professor Rowlee made plain to his hearers all the intricate processes in the nutrition of plants. Nevertheless, on these and other subjects alert, level-headed men and women familiar with all the phenomena of plant-growth will very readily seize upon some fundamental scientific principles which will aid them very materially in their every-day work. Not only will new ideas throw new light on the reasons for their practice, but it will lead them to inquire for more knowledge as they attempt to adjust their practice to their new-found

knowledge, and, more than that, the substantial and indisputable truths here acquired will probably avail to keep them from many costly mistakes by showing them the impracticability of projects which to the utterly uninstructed might seem promising.

We are glad that the first horticultural institute of this sort has been held under such favorable auspices. We consider it a step forward in the means and methods of popular instruction. A little knowledge is not a dangerous thing when it is rudimentary and fundamental knowledge. The dangerous kind referred to by the poet is a superficial smattering.

Notes on the Tree Flora of the Chiricahua Mountains.—II.

ASCENDING the cañon, on the mountains at either side, were large areas of Scrub Oak, including *Quercus undulata*, *Q. hypoleuca* and *Q. chrysolepis vaccinifolia*. Two other Oaks, *Q. Gambelii* and *Q. reticulata*, were found farther up among the Pines and Cypress. *Quercus Gambelii* is known as Pin Oak, and, although here a small shrub, produces a trunk eighteen inches or two feet in diameter farther north. *Q. reticulata* is also generally a shrub, but in moist places in deep cañons it not infrequently approaches a tree in size and habit. This species, although very near *Q. grisea* in specific characters, is quite different in general appearance. The bark is much smoother, the foliage a deeper green, and the cups, with their long peduncles, remain on the branches several months after the acorns have fallen. In July the peduncles of the former year were still on the branches. An Oak was found at old Camp Rucker which has been referred to *Q. grisea*, but which has the general aspect of *Q. oblongifolia*. It has the same bluish cast to the leaves, and but little roughness on the under surface. The peduncles are long, something like those of *Q. reticulata*. By examining the acorns of these three species it will be seen that they are almost identical. They are very astringent, and the cotyledons are a deep purple color.

Yucca macrocarpa was found in abundance throughout the south and central portions of this range. It is strictly a mountain plant, frequent in shady cañons at an elevation of from three to six thousand feet. This species seldom gets beyond the foot-hills, and is in full bloom by the 20th of July and ripens its fruit by the 10th of September. *Y. baccata* is a more northern plant, but covers large areas on the east slope of the Chiricahua Mountains between Gayleyville and Fort Bowie. Its habit of growth is entirely different from *Y. macrocarpa*. The caudex, if at all long, lies prostrate on the ground, while *Y. macrocarpa* is always upright. *Yucca elata*, the most widespread *Yucca* of Arizona, is frequent on the mesa at either side of this range. It is a plains plant, and never found in the mountains. It reaches its maximum size in south central Arizona, and is in full bloom by the first of June, and ripens its fruit a month or six weeks later. The *Yucca* of the Colorado plateau, which has been referred to this species, is quite different, and should, I believe, be considered a new species.

Two arborescent species of Cacti—namely, *Opuntia arborescens* and *O. fulgida*—are frequent in the valley west of the mountains. Both of these species form small trees, with trunks sometimes eight or ten inches in diameter.

A few miles below old Camp Rucker the first Pines were observed, and from here they increased in size and frequency almost to the summit. The first species observed were *Pinus cembroides* and *P. Chihuahuana** (see page 24). Several miles above the old camp were many large speci-

mens of *P. latifolia*† (see page 25) and *P. ponderosa*. I am inclined to the opinion that all the long-leaved, broken-cone Pines of southern Arizona are at most only varieties of *Pinus ponderosa*. There seems to be all variations, from the long-leaved to the short-leaved forms.

Abies concolor, *Pseudotsuga taxifolia* and *Cupressus Arizonica* were not infrequent in the cañons above five thousand feet. The Arizona Cypress is a rare tree, only growing in a few of the mountain ranges of the territory. The largest specimens observed here were eighteen inches in diameter and fifty feet high. There is a large grove containing many thousand of these trees at the Natural Bridge in central Arizona. They are very symmetrical, and many of them fully three feet in diameter. The bark has a reddish cast and peels off in long shreds. This character, however, was not observed in the specimens seen in the Chiricahua Mountains.

I much regret that I was unable to get to the highest point of these mountains, as there are probably trees growing there which are not in the following list. I was informed by a Mr. McGraw, a ranchman thoroughly familiar with the mountains, that a White Pine and a Larch were growing at the summit. It is not improbable that a White Pine, probably *Pinus reflexa*, does grow there, as it is found in many of the other ranges of southern Arizona. I seriously question the possibility of finding a Tamarack there.

In Turkey Creek cañon, which opens toward San Simon Valley, just south of Fort Bowie, were fine specimens of *Acer barbatum grandidentatum*, *A. Negundo* and *Prunus serotina*. This latter species shows a great variation in the size and flavor of the fruit. The trees in this cañon were especially noticeable for their large fruits, with comparatively small pits. It is not impossible that this species might be made of considerable horticultural importance.

Cercocarpus parvifolius paucidentatus and *Rhamnus Purshiana tomentella* are frequent throughout the entire range. The former appears very different from *Cercocarpus parvifolius*, and very likely is specifically distinct. Large areas of San Simon Valley are covered with a stunted growth of *Prosopis juliflora* and *Koeberlinia spinosa*. The spines of the latter species are said to be poisonous, and produce a stinging sensation when they pierce the skin.

I append a list of the trees collected in the Chiricahua Mountains and in the adjacent valleys. Of course, it is understood that a large percentage of this list were observed in several of the ranges visited. It is quite remarkable that this one range in the very south-eastern portion of Arizona has over fifty species of trees, or more than one-ninth of the total number in the United States :

Condalia obovata, *Koeberlinia spinosa*, *Rhamnus Purshiana*, *Rhamnus Purshiana tomentella*, *Acer barbatum grandidentatum*, *A. Negundo*, *Sapindus marginatus*, *Acacia Berlandieri*, *A. Greggii*, *Robinia Neo-Mexicana*, *Prosopis juliflora*, *Parkinsonia Torreyana*, *P. microphylla*, *Eysenhardtia orthocarpa*, *Prunus serotina*, *Vauquelinea Californica*, *Cercocarpus parvifolius paucidentatus*, *Cereus giganteus*, *Opuntia arborescens*, *O. fulgida*, *Sambucus Mexicana*, *Arbutus Arizonica*, *Bumelia spinosa*, *Fraxinus velutina*, *Chilopsis saligna*, *Celtis Mississippensis reticulata*, *Morus celtidifolia*, *Platanus Wrightii*, *Juglans rupestris*, *Quercus Gambelii*, *Q. undulata* (several widely varying forms), *Q. oblongefolia*, *Q. grisea*, *Q. reticulata*, *Q. chrysolepis vaccinifolia*, *Q. Emoryi*, *Q. hypoleuca*, *Q. n. sp.*, *Alnus oblongifolia*, *Salix nigra*, *S. longifolia*, var., *S. sp.*,

* This species, which is well distinguished from all other Pine-trees bearing their leaves in clusters of threes by the deciduous-leaved sheaths, was discovered by Wissler on the mountains of Chihuahua, and first described fifty years ago by Dr. George Engelmann, to whose long and patient studies we are indebted for much exact information on the Pine-trees of western and south-western North America, the great headquarters of the genus. Much later, *Pinus Chihuahuana* was found on several of the mountain ranges of southern New Mexico and Arizona, where, scattered among *Pinus Arizonica*, *Pinus ponderosa* and *Pinus reflexa*, near the upper borders of the Live Oak forests which cover the lower slopes of these mountains, it is a comparatively rare tree, and seldom grows to the height of sixty or seventy feet. The wood is soft and brittle, and *Pinus Chihuahuana*, although it possesses considerable scientific interest, has little economic significance as an inhabitant of our forests.

† In vol. ii. of GARDEN AND FOREST (page 408) this Pine tree, closely related to *Pinus ponderosa*, which had been found by Dr. Henry Mayr, the German forester, some time previously on the Santa Rita Mountains of Arizona, was described and figured. It is distinguished by its very long broad leaves and by the stout recurved umbos of the more or less mammæformed basal cone scales; and in these characters appears very unlike forms of that well-known and very variable tree from more northern regions. There is such resemblance to other forms of *Pinus ponderosa*, however, in the bark, habit and general appearance of this Arizona tree which were not known when Dr. Mayr's specimens were described that it is not improbable, when this western American Yellow Pine group is studied in all its forms, that it will be necessary to include among them the long-leaved Arizona tree, of which there are two or three remarkable varieties. On the Santa Rita, Huachuca and Chiricahua Mountains this tree is not rare at elevations of about seven thousand feet above the sea, where it grows on stony slopes with a short-leaved variety of *Pinus ponderosa* just below the belt of *Pinus cembroides*, which covers, with a rather dense forest, the highest slopes of these mountains.

Populus tremuloides, P. *Fremontii*. *Cupressus Arizonica*, *Juniperus pachyphylcea*, J. *occidentalis monosperma*, J. *Virginiana*, *Pinus reflexa*, P. *cembroides*, P. *Arizonica*, P. *ponderosa*, P. *latifolia*, P. *Chihuahuana*, *Pseudotsuga taxifolia*, *Abies concolor*, *Yucca elata*, Y. *macrocarpa*.

Tucson, Arizona.

J. W. Toumey.

An Indian on Indian Corn.

THE Penobscot tribe of Indians, on the Penobscot River, some three or four miles above the city of Bangor, Maine, has a considerable "reserve," consisting chiefly of some large islands. Some of these Indians are farmers, though most of the men are engaged in lumbering, which is extensively carried on at that point. They have very good schools, and as I have several times taken the up-river train in the morning from Bangor, I have been pleased in observing the well-dressed and intelligent-looking Indian girls and boys who avail themselves of the same train on their way to school. They do not seem in any way inferior to their white companions on the same train, either in the neatness of their apparel or in general good looks.

I have also had an opportunity of becoming personally acquainted with a few of the leading men of the tribe, and with one of these, Mr. Peol Susup, I have corresponded on a number of subjects, one of which was Indian Corn. I had been trying to develop and improve the dwarf and early varieties which are alone suited to the elevated north-eastern portion of Vermont, and in reply to my inquiries Mr. Susup wrote to me as follows :

Indian Corn is called by the Indians Weachin, and it is believed to have originated in Mexico. When white men arrived in America they found it in cultivation from latitude forty degrees south to the island of Orleans, in the St. Lawrence River. That was probably its extreme limit in the north-east. How it could have been propagated and ripened so far north of its native tropical home has been a subject of curious speculation. Every cultivator has doubtless noted how difficult it is to perfect the plant from seed obtained at any considerable distance south of the region in which he endeavors to raise it. Seed procured from New York will seldom or never perfect itself in Maine, and it is deemed unsafe to plant that brought from Massachusetts. How, then, did the Indian, without other agricultural education than that derived from his own unrecorded and imperfect observations, push its production from the Gulf of Mexico to the St. Lawrence? He certainly accomplished this result ages before the white man visited him; and it was to the natives that the early white settlers of New England were indebted for their seed corn of the varieties now in use.

An annual plant may extend itself east, or west, along isothermal lines, by accidental causes; but it could not have moved into a colder climate, requiring cultivation and care, without great attention, and the application of more than ordinary skill. It must have required ages to have been acclimated in that country now constituting Canada and the New England states.

The Indian has a tradition regarding the method by which the northern varieties of Corn were obtained and perfected. Like all the grasses, and many other annual plants, Corn grows upward by joints or sections. The Indians observed that the time required to produce and perfect a joint was one change of the moon; and as the ear of corn starts only from a joint there was necessarily about seven days between the forming of the ears on successive joints. Now, if an ear can be made to start at the second joint, it would mature some five weeks in advance of that which should be formed on the seventh joint. By constantly selecting for seed the lowest ears, he finally obtained varieties that produced from joints lower than the original plant, and very much earlier. Thus, in time, corn was produced, small in stalk and ear, and adapted to the short summers of the north. Slowly, but permanently, it passed into the eight-rowed corn, producing constantly on the lower joints, and ripening in three months from the day of planting.

I may add to Mr. Susup's account an early memory of my boyhood. My grandfather was, in 1792, an emigrant from the valley of the lower Connecticut River, near Windsor, Vermont, to Kennebeck County, Maine. He found it diffi-

cult to obtain at that time any variety of Corn that was safe to grow, even in south-western Maine; but later he supplied himself with a sure-ripening variety called the Canada Creeper, which produced its ears very near the ground. In the elevated region of north-eastern Vermont, where I have now lived for nearly thirty years, I found the same trouble, and surmounted it in the same way; but by careful selection I have greatly increased the length of the ears, and the consequent productiveness, without lessening the earliness of the crop. My annual yield of this corn, when dry and shelled, is rarely as low as fifty bushels an acre.

Foreign Correspondence.

London Letter.

ARUNDINARIA MACROSPERMA (*A. tecta*) is a North American Bamboo, which is very much wanted by growers of hardy Bamboos in this country, but at present it cannot be obtained for love or money. None of the American nurserymen catalogue it, and none of the many likely people in America who have been asked to send plants of it have so far responded, until it has been questioned whether this Bamboo is to be found in the United States after all. We have all read of "cane-breaks," and have been informed that they are formed of big stretches of *A. macrospurma*. Is it possible that they have all disappeared? If not, and there are plenty of plants of it to be got for the digging, I would recommend some enterprising nurseryman to advertise the plant at so much per hundred in some English horticultural paper, and, unless I am much mistaken, he will have reason to be glad for this suggestion. We have a clump of it at Kew, where it is perfectly hardy and evergreen, and, consequently, is much coveted by the majority of those who see it here.

RHODODENDRON KEISKEI.—This species was described by Maximowicz in 1870 in a paper published in the *Memoirs of the Academy of Sciences*, of St. Petersburg. Plants of it are in cultivation at Kew, and one of them has lately flowered. In the form and color of the flowers it most resembles *Rhododendron Dauricum*, which flowers in winter, but there is a marked difference between the two in habit and foliage. *R. Keiskei* is dwarf in habit, with trailing branches, biennial, elliptic, ovate, leathery leaves three inches long, green above, clothed with reddish lepidote spots below. The flowers are in loose corymbs of from three to five; calyx lobes nearly obsolete; corolla campanulate, an inch across, colored rose-purple; stamens ten, declinate, the filaments slightly hairy at the base. The plant is quite hardy at Kew, and, judging from Maximowicz's description and figure, it is likely to prove at least as useful as *R. Dauricum*. It is a native of Kyushu and of Hondo, where it is sometimes cultivated in the gardens of Tōkyō.

KNIPHOFIA NATALENSIS.—This species was first described some eight years ago from specimens sent to Kew by Mr. Medley Wood, of Natal. A plant of it from the same source flowered in a cold greenhouse at Kew in June, 1889, the scape in this case being two and a half feet long, bearing a loose spike of drooping orange-yellow flowers an inch long. A short time ago Herr Max Leichtlin sent to Kew a plant which he thought would prove to be a new species. He had received it from Natal. With him it flowered in winter, and had leaves four feet long. It is now in flower at Kew, and while it does not specifically differ from *Kniphofia Natalensis*, it is superior to the type in having the flowers much denser on the spike, and in their color being a uniform citron-yellow. If it should prove to be constant in flowering in midwinter it will prove a useful plant for the conservatory. There are now about thirty species of *Kniphofia*, or double the number known in 1870, when Mr. Baker monographed the genus. The extremes of the genus are represented by the gigantic *K. Nothiae* and *K. aloides* on the one side, and the tiny *K. pallidiflora* and *K. pauciflora* on the other. They are all worth a place in the garden.

HOWARDIA CARACCASANA.—The genus Howardia, or Pogonopus, is nearly allied to *Pinckneya pubens*, the beautiful Rubiaceous tree found wild in Florida and Carolina, but, so far as I know, never yet successfully grown in England, notwithstanding numerous earnest attempts. The Howardia under notice is not, however, so recalcitrant, for it has flowered at Kew several times within the last twenty years, and it is in flower now. It grows to a large size if allowed to, Mr. Howard, the Cinchona expert, after whom it was named by Weddell, having grown a large bush of it in his garden at Tottenham. The plant in flower at Kew now is only eighteen inches high; it has opposite, stalked, light green leaves and terminal loose panicles of tubular pink flowers an inch long, subtended by foliaceous bracts colored rose-pink, with yellowish tips. The genus *Mussænda*, also Rubiaceous, has the same peculiar character, but in that genus all the species have white bracts and comparatively small yellow flowers. The Howardia is a meritorious winter-flowering stove plant. There is a good figure of it in the *Botanical Magazine*, t. 5110 (1859), where it is described as "a very lovely stove-plant with gracefully drooping panicles of flowers, whose beauty is very much increased by the remarkable enlargement of one of the teeth of the calyx into a heart-shaped, petiolated, deep rose-colored, foliaceous lobe." It appears to have been distributed by Messrs. Makoy & Co., of Liège, many years ago under the name of *Pinckneya ionantha*.

DRACÆNA GODSEFFIANA is a stove-plant of exceptionally pleasing and distinct character. It is represented by hundreds of plants in the St. Albans nurseries and will shortly be distributed by Messrs Sander & Co. as a new foliage-plant. I have already called attention to it in GARDEN AND FOREST, but it is good enough to be mentioned again. It is a true Dracæna, not a Cordyline, the correct generic appellation of the plants known in gardens as *D. terminalis*, *D. indivisa*, *D. recurva*, etc., and most resembles the old *D. surculosa*, for which it was at first mistaken. Now that it is in character, however, its distinctness from all other cultivated representatives of this genus is very evident. It has thin wiry stems, branches and suckers freely, and its ovate, elegantly waved leaves are colored glossy green, with numerous large spots of creamy white, suggesting in variegation the leaves of a good variety of *Aucuba Japonica*. It is easily propagated from stem-cuttings or by division, and it grows freely. It is a native of Lagos, whence it was introduced about three years ago.

TEA CULTIVATION.—The monopoly of the tea trade by China has long since been broken down, the tea plant being now cultivated in India, Ceylon, Natal, Mauritius and other countries with more or less success. Its cultivation under glass in England even has been suggested as a profitable undertaking. Russia, hitherto China's best customer for the choicest teas, has lately started tea plantations in Batoum, and, according to a recent consular report to the British Foreign Office, with every prospect of success. Chinese tea-planters have been employed to foster the industry, and in less than ten years the experiment has been productive of such satisfactory results that the Russian Government has set apart 43,000 acres to be turned into

tea plantations. The methods of tea culture in practice in Ceylon, India and China are to be thoroughly studied by a commission sent for the purpose to those countries. The Chinese tea-plant, *Thea chinensis*, now called *Camellia theifera*, is hardy against a wall at Kew and forms a dense shrub six feet high in the temperate house. There is no reason, therefore, why it should not be cultivated with success wherever the Orange, Olive, Pomegranate, Persimmon and such like plants thrive in the open air. I am not aware if tea cultivation is an established industry in the southern

Fig. 3.—*Pinus Chihuahuana*.—See page 22.

United States, but if it is not, the experiment is well worth making. The Indian variety, *T. Assamica*, now called *Camellia theifera*, var. *Assamica*, is not so hardy and thrives best in an almost tropical climate. Tea seeds are easily imported from India or Ceylon and they germinate readily. The Assam variety was thus obtained by Kew and distributed to Mauritius, Jamaica, Natal and other colonies a few years ago, the seeds afterward germinating freely. Cultural directions are easily obtained, but I should say that a good loamy soil, a moderate supply of water, bright,

warm sunshine in summer and a minimum winter temperature of about twenty-five degrees, Fahrenheit, are the conditions most essential to success.

London.

W. Watson.

Plant Notes.

LONICERA STANDISHII AND L. FRAGRANTISSIMA.—We place these two Bush Honeysuckles together because they are both of Asiatic, probably Chinese, origin, and are so closely allied that they may ultimately be classified as varieties of

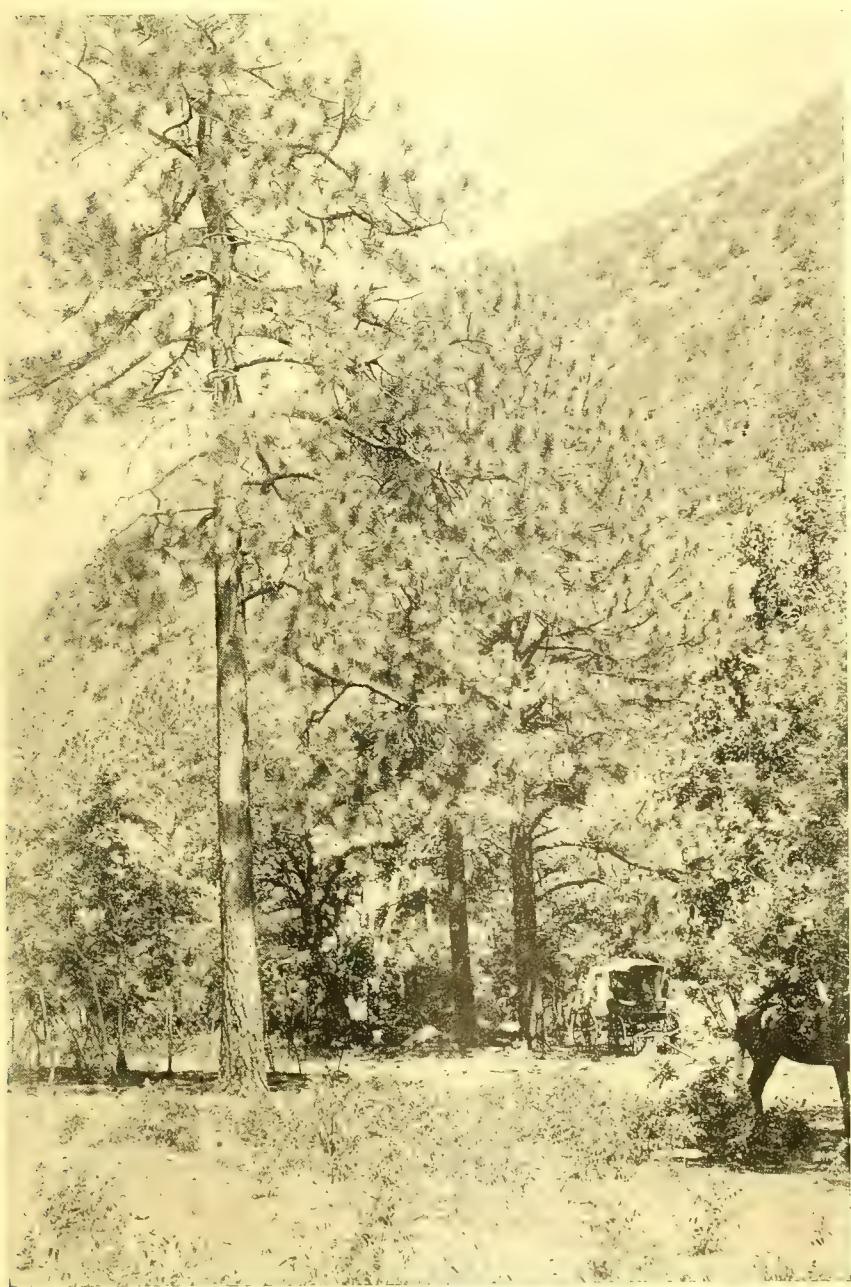

Fig. 4.—*Pinus latifolia*.—See page 22.

a single species. *Lonicera Standishii*, which was introduced into England by Fortune, who found it a common garden-plant in Shanghai, is somewhat the hardier of the two, and its deciduous leaves indicate that it is of more northern origin. Both plants hold their leaves well into the autumn, but *L. fragrantissima* is nearly evergreen in Philadelphia, and, perhaps, entirely so not far south of that latitude. Both species open their flowers very early here, before the appearance of their leaves, and sometimes the flowers appear quite abundantly in autumn before all the

leaves have fallen. Fortune's plant was used quite generously in the original plantations of Central Park, and its white flowers are often seen in warm days in February, while their abundant bloom in April makes this Honeysuckle a feature of the park shrubberies. The flowers of both species are white, although there is a tendency toward rose-color in some individuals of *L. Standishii*. Some of the buds on both plants seem ready to open almost any warm day in winter, and if the twigs are cut off and placed in water in a warm room they will soon fill it with their fragrance, which resembles that of violets. It is noteworthy that this fragrance is quite as marked in the precocious flowers which appear in autumn as in those which wait until their regular season. Both these Honeysuckles are tall, stout-growing, twiggy shrubs with yellow-brown branches. Occasionally, after a mild winter, in which the buds have swelled more than usual, they are blasted by very cold weather in the spring, but there are usually enough remaining to open later and give a fair amount of bloom. In a good season it is not uncommon to find ripe berries among the open flowers in May.

ACACIA PUBESCENS.—We have often spoken of this old plant, which was introduced into cultivation more than a century ago, but it is worth repeating here; that for certain purposes it is one of the very best of this large genus, and a well-grown specimen can hardly be excelled in grace of form. Seedling plants are the strongest. They make roots rapidly, and should be shifted on until the specimens occupy a large tub. When trained to a single stem they will attain the height of about ten feet, and the head will expand into as great a breadth, with drooping branches thickly hung with racemes of small globular sulphur-colored flowers, which appear to the best advantage among the delicate Fern-like foliage. These flowers, too, are delightfully fragrant. The plant is not particular as to soil. After the flowering season, which begins in February and lasts for about six weeks, the branches should be cut back, so that a specimen can be kept within the limit of convenient size for many years, and if the soil is well top-dressed it will always be in first-rate flowering condition. The natural habitat of the plant is southern Australia, and it can be kept in any house where the temperature does not fall below forty. The best treatment for young plants is to plunge them out-of-doors somewhere under a lath shelter, as they prefer a partial shade.

CLEMATIS RECTA.—This is a well-known herbaceous perennial, making a compact plant three or four feet high, and larger still when it has become well established, which

is covered in June with many-branched clusters of small, densely crowded flowers, which are creamy white, and fragrant. Old plants which have remained undisturbed for years are quite effective in a herbaceous border among tall Delphiniums and other plants which flower at this season. It is a native of southern Europe and has been cultivated for its flowers in English gardens for three hundred years. We make mention of it at this time, having recently seen a plant which soon promises to bloom under glass. The roots of the plant, which was a seedling three years old,

was set in a large pot last spring and planted in the border, where it flowered as usual. After some hard freezing it was brought in and slowly started, and it is now a strong-looking plant, grown in a cool temperature and ready to be hurried on to what promises to be a successful blooming. It is doubtful whether the flowers will be worth the trouble of producing them, but they may be useful when cut to arrange with other flowers of strong colors. There are so many plants which can only be flowered under glass in this climate, that it seems hardly worth while to select those which will flower as well or better in the open air if they are only left alone.

Cultural Department.

Notes on Carnations.

IF cuttings of the varieties of Carnations to be grown for summer blooming outdoors have not already been set, no time should be lost in getting them in. Some growers lift old plants from their benches and plant outside, and thus obtain a moderate supply of small early blooms, but the plants are always rather unsightly, and so much finer flowers are produced from cuttings rooted in December or January that old plants are best consigned to the rubbish pile. Comparatively few varieties flower satisfactorily outdoors. Among the white kinds, Mrs. Fisher does well, and easily leads all others for outside culture; Nobsco, as a scarlet, does remarkably well here; Hector blooms very freely, but the flowers burn badly. We have not yet found a thoroughly satisfactory pink variety, William Scott being the best we have tested. Ferdinand Mangold gives a fair supply of crimson flowers. Among yellows, we have not been able to obtain good results from any variety yet tried.

Many Carnations are utterly ruined in the early stages of their existence by being propagated in too strong a bottom-heat; weak, spindling plants are always the results of such propagation. An even bottom-heat of sixty degrees and a top-heat of fifty to fifty-five degrees we consider the best. If a propagating bed with such a temperature is not at command the cuttings will root well in a well-drained box of sand placed on the shelf of an ordinary greenhouse. The cuttings must never be allowed to get at all dry; a sprinkling overhead should be given daily, and a thorough soaking every third or fourth day. With proper care ninety per cent. of the inserted cuttings should take root. Some kinds root much more quickly than others. Mrs. Fisher, Nicholson, Nobsco, Ada Byron and some others are fit to pot or box off in about a month from the time they are inserted, while F. Mangold and some of the yellow varieties require a much longer time.

For winter-blooming plants we consider February early enough to put in cuttings, except of such delicate growers as Lizzie McGowan. In taking a tour round some Carnation establishments of late, we noticed thousands of cuttings rooted in the cutting-benches and quantities boxed off. We found that the growers in every case had raised this stock for sale; their own stock of cuttings would be got in later. Of course, it is perfectly natural for trade-growers to commence propagating as early as possible and sell all the stock they can, but we do not believe that plants grown from cuttings inserted in November, December or the first half of January are as good as those raised later in the season. Allowing that the plants are already rooted and ready to box off, some four months must elapse before they can be planted outside (at least in this section), and whether in pots or boxes, this is far too long a period for the young plants to have their roots cramped. The idea often is that as large plants as possible should be grown by lifting-time in the fall, but medium-sized ones are much better to handle, tie up, and clean, and give furthermore fully as fine blooms and as many of them as the larger ones, in proportion to the space they occupy.

Plants in the benches should now be gone over, untied and cleaned. It pays to do this at least twice in the season. In cleaning them we remove all dead and decaying leaves, and also the weak and spindling growths. These growths are best removed; they give but poor flowers, and their removal gives the remaining shoots a better chance. Care ought to be taken not to tie up the plants too tightly, this spoils many of the young growths. Some growers do not stake or clean their plants at all, and we have seen very good flowers on such plants until spring, when the superiority of those cleaned and staked is apparent to the merest novice. With increasing sunlight the benches will now require rather more frequent waterings, and slightly stronger liquid stimulants can safely be given.

A surface-dressing of wood ashes or some chemical fertilizer, alternated with a watering of liquid-manure or sulphate of ammonia of moderate strength, every ten days or fortnight, will be found very helpful. If good flowers are desired, disbudding should be practiced. This may not be a profitable thing for trade-growers, but it pays in a private establishment where quality is the first requisite. The operation ought to be performed as soon as the buds can be handled.

Among pink Carnations this season William Scott takes the lead; it gives twice as many flowers as any other pink variety, and seems destined to entirely supersede that worthy old favorite, Grace Wilder. This variety has a good stem and good-sized flower, with a strong calyx; its lack of odor is its only drawback. Madame Diaz Albertini has a remarkably strong stem, the stoutest of any pink-flowering sort we have grown. Its flowers are of large size and of a delicate flesh-pink color, with a strong calyx and a delightful odor. The flowers hold well on the plants, which, however, do not bloom so freely as some other kinds. Nicholson gives us the largest flowers of any pink variety; its bright color and fragrance have made it very popular in the Boston market; it needs a stronger stem, however. Ada Byron has the finest odor of any Carnation we grow; the flower is of good size and beautifully fringed; the plant is of a very vigorous growth, but is a poor winter bloomer. Daybreak still retains its great popularity; with some it rusts badly, but with others it is this season doing remarkably well. Among scarlets, Hector is still the best we have; Portia produces more flowers, but they are not over half the size of the other variety. The Stuart has the ideal stem for a Carnation, and is of a good scarlet shade; it is not so good a flower as Hector, however, and blooms less freely. F. Mangold still holds the lead among crimsons. Lizzie McGowan proves itself the most reliable white; it does not produce so many flowers as Mrs. Fisher, but they are of a purer white color; its stem is better, and it seldom bursts the calyx. Helen Keller seems destined to be a very popular kind, but the plants make rather poor growth; it is the best fancy kind at present on the market. Bouton d'Or, from what we have seen of it, is likely to prove a very popular yellow; the flower is of good size, deep canary-yellow in color, slightly flaked and bordered with carmine; it makes good growth, has a strong calyx, and is, so far, perfectly healthy. Goldfinch, one of Mr. Dorner's introductions, is also a fairly good yellow, which blooms freely; the flowers, however, are much smaller than those of Bouton d'Or, and it is hardly worth growing where the other kind will succeed.

W. N. Craig.

CARNATIONS generally, in the neighborhood of Boston, never looked better, and the prospects are that growers hereabouts will make a first-rate display at the forthcoming exhibition of the Carnation Society in Boston next February. Mr. Nicholson, of Framingham, has his William Nicholson and Ada Byron in excellent condition, and they fully maintain in the market and everywhere the reputation they made last season. Some very promising new varieties are also on trial. Mr. Fisher and Mr. Nicholson will show some new scarlets, whites and crimsons, now under number; Mr. Tailby, some yellows, notably Henrietta Sargent, a good pink and a white. The Messrs. Jaune Brothers, of New Bedford, and Mr. Denys Zirngiebel, of Needham, have some fancy varieties which they expect will win favor.

Some rust showed in one or two places this season, but is disappearing with the lengthening days. With regard to this disease, growers agree that cleanliness is the best prevention and remedy. All admit the efficacy of sulphur compounds, and use them, but experience proves that when once the plants are badly affected this treatment is of little apparent benefit. In a visit to a number of growers of Carnations, I found the disease to be worst where the plants were wettest. It is natural to suppose that a lack of root-action and the consequent lessened elimination of moisture will encourage the spread of disease. One grower attributed the poor condition of his plants to overwatering, I, myself, should add, overfeeding, in the earlier stages. The finest plants I have seen have not yet had any stimulants, but with increased sun-power some fertilizers will be given. The best success is had with plants which are kept dry rather than wet, but it is evident that where the root-action is good the plants will quickly become dry.

On the question of soils there is one opinion, and that is, that light soils are best for nearly all varieties. Lime is essential in some form. It is an ingredient of nearly all soils, and thus it is only especially necessary to apply it on heavy soils, and it is generally found in sufficient quantity in all barnyard manures. I was surprised to learn, however, that one grower had failed with William Scott, which almost everywhere has

proved the best pink Carnation. As a reason it was stated that his soil is heavy. This same grower is now taking the best Daybreaks and Ferdinand Mangolds into the Boston market, which would indicate, as has generally proved the case elsewhere, that heavy soils are better for some varieties than for others. Still, it is surprising with regard to William Scott, introduced by Dorner, whose soil, I am informed, is heavy, and that few of his introductions succeed elsewhere on that account.

Mrs. Fisher is still the best all-round white variety, and the most profitable, being also an excellent summer variety. This variety is not grown extensively beyond the limits of the Boston trade. Lizzie McGowan is considered the best white about New York. The difference in choice lies more in the methods of cultivation than in any other particular. If Lizzie McGowan flowered for a longer season, no variety could be more profitably grown, according to New York florists. It is a rather slender, "grassy" grower, and does not take up as much room as Mrs. Fisher, and it may be planted earlier. It needs to be propagated and planted earlier for best results. Tidal Wave is a popular market variety of a deep rose shade, and, although discarded for a time in favor of some of the newer introductions, which it was supposed would supersede it, it is now again coming into favor. It is an abundant producer, but lacks a good stem. E. G. Hill has gradually grown in favor. It is a good clear scarlet of medium size and graceful outline. The stems are long and stout, and the flowers bear few side buds, an important qualification of a good Carnation. In size of flowers, vigor and abundance of crop it does not come up to Hector; some proportion of the latter, however, burst the calyx, a serious defect. Daybreak has become a popular Carnation, and justly so. The color is an attractive shrimp-pink, its flowers extra-large, with stems two feet long. When introduced three years ago it showed a decided tendency to rust, and was not considered as promising as it has since proved. It is looking well everywhere, and carries an abundant crop. Nicholson is another magnificent light pink of different shade, with a tinge of salmon. Ada Byron has not given general satisfaction with the majority of growers, but with the introducer it is a wonderful variety, and, without doubt, the most beautiful in form and the most fragrant of all Carnations. Ferdinand Mangold is still the best crimson.

Uncle John, the Stuart and Jacqueminot are not favorites now, but it is to be hoped the introducers will vindicate themselves at the forthcoming exhibition.

Gloxiniyas.

THIS is a suitable time to sow seed for a crop of these beautiful flowers. Well-drained seed-pans are required, with a mixture of equal parts of loam, leaf-mold and sand, that on the surface being finely sifted. The pan should be stood in water until the soil is thoroughly wet through, and the seed sown on the surface and left uncovered. A pane of glass should be placed over the pan, and over this a sheet of brown paper, the latter being removed after the seeds have started. As the seeds are very fine, the pans should never be watered from the surface. It is preferable to dip the pan, and to have the water soak up from the bottom until it begins to appear on the surface. A warm moist atmosphere is most favorable to germination. When the plants are large enough to handle they should be pricked into boxes containing the same mixture of soil as before, and finally planted into pots with a little dried cow or sheep manure added to the mixture. They should be kept growing as freely as possible, and all flowers pinched off as they appear, except, perhaps, one on each plant to show the variety, so that those not worth growing may be discarded. In the fall they should be ripened off gradually, and the tubers stored away in a dry place in a temperature not exceeding fifty degrees. Toward the end of December they will show signs of starting, and should be planted in boxes in a mixture of sand and leaf-mold and sprinkled lightly until their growth is well begun, when they should be potted singly into small pots at first, and shifted on as they require it. The potting compost should be as open as possible, the pots well drained, and water should be given carefully. The secret of success lies in keeping the soil sweet and free from stagnation. It is not advisable to sprinkle the foliage, since the leaf, being downy, retains the moisture too long. This is the main cause of rust, to which these plants are subject. Gloxinias should be kept in a light position near the glass, but they are benefited by a slight shading from strong sunlight. A temperature of sixty degrees should be maintained by night, with

a rise of ten degrees by sun-heat, and fresh air should be admitted at every favorable opportunity. Much can be done toward the improvement of varieties by careful selection and hybridization. We raise a batch from seed every year, and get the best results from the tubers the second year, and, with the exception of a few of the finest varieties, we seldom keep them longer than two years.

William Scott.

Mushrooms.

WE often hear of failures in the cultivation of this vegetable, and among the main causes are (1) that the spawn is not good, (2) that the droppings were not in the right condition, and (3) that the bed has been kept too dry or too wet. It is of the first importance that the spawn be fresh. If it has been kept in a store for a long time it is likely to have thick white fibres running through it; these show that it has at some time been kept warm and started to run, which should not occur until it is in the bed. If, on the other hand, it has fine tissues of fibre all through it, it is in the right condition. Another guide as to freshness is that fresh spawn is not hard and that it has a fresh odor.

Two methods are generally followed in preparing the droppings for the bed. These are drying by exposure and drying by heating. I prefer the latter method for the reason that the main object in drying them is to obtain a gentle, lasting heat, and when they are put through a regular course of heating this brings out the rank heat better than when they are dried by exposure. Have as many droppings as will make the size of bed that is desired, discarding all the long straw that can conveniently be separated from them. They should be thrown into a heap and stand until they get hot and begin to have a whitish appearance on the inside of the heap. They should then be spread out thinly, and they will regain their natural color when they are cooled off. They should be treated in this way two or three times until there is no sign of moisture when they are squeezed in the hand; they will then have a pleasant odor.

The bed should be made from one foot to fifteen inches in depth. A good layer of the droppings should be put in and beaten down until it is firm. One layer after another should be added until the required depth is gained. It is desirable to mix a little sifted loam through the droppings since this keeps the heat down and the spawn runs well in it. A convenient rammer is made of a piece of hard wood five inches square and nine inches long, with a short handle in the middle.

The bed must stand a few days before the spawn can be put in, to let the heat rise and decline, for a bed should be spawned only as the heat declines. On this rise and fall of temperature depends much of the future success, for if the heat rises too high it will just as surely fall too low. I prefer that it should not get much above ninety-five degrees, and the heat is retained much longer if the spawn is put in at eighty-five degrees on the decline. Of course, the closer the pieces of spawn are set the more mushrooms may be expected. About six inches apart each way is a good distance. The spawn should be broken into pieces about two inches square, buried two inches deep, and the bed made firm. The edges of the bricks seldom contain much spawn. About one inch of good loam should be put on the top and firmed down with a spade, and a gentle wetting with tepid water should be given; the water should always be of the same temperature as the bed. If the spawn is dry the bricks should have a gentle watering some hours previous to using them. The bed should have a good covering of hay or similar material, which will retain the moisture as well as the heat. The bed should be watched, and if the hay gets moldy it must be taken out and dried, and if the surface of the bed becomes dry syringing is generally all it will require. If on examination the bed is found dry it should be watered, but drenching must be avoided, as this is injurious. Mushrooms appear in a month to six weeks from spawning, and when they show, a watering of dilute nitrate of soda is beneficial; this causes them to grow quickly and prolongs the season of production. The application of nitrate of soda should be repeated every ten days or two weeks until the bed is spent.

Any place which can be kept dark and near an even temperature of fifty degrees will suit them. A cellar is one of the best places. Mushroom-houses are sometimes placed near the boiler-house; this is radically wrong, causing a dry heat, and making frequent dampings necessary. Mushrooms delight in a moist atmosphere, and well repay attention in this particular.

Correspondence.

Variety versus Monotony.

To the Editor of GARDEN AND FOREST:

Sir,—The article in the issue of GARDEN AND FOREST for November 28th, signed "M. C. R." is full of suggestion and good advice, but I do not endorse the view put forward that a garden filled with a variety of plants, aptly termed a museum, is a place of weariness in comparison with the garden made up of a few bold groups. The charm of the garden is that it is full of change, and herein it differs from the forest or the park, with its wide breadths of tree or shrub. When I go into a garden I look for interest, not a grand effect merely, not a monotone. In such places as M. C. R. prefers one may walk with enjoyment, but after the first view one's thoughts or conversation are generally of other things than those we see. But in the well arranged garden, rich in its collections of plants, there is a running stream of interest and pleasure as one passes from one object or group to another. I maintain that a garden should be a museum first and a picture afterward. This is also true of parts of the garden, such as border, flower-bed, shrubbery or tree group. A border filled with red roses only may be a grand picture, but it fails to interest as the mixed border does, which we examine from end to end. In large gardens broad effects are easy, but they ought not to be repetitions of the same or a few plants. In the smaller garden these broad effects are not possible, unless one wishes to be thought eccentric. I sometimes walk in Richmond Park, the finest of our metropolitan parks, in which the groves of Oak and Fir that Repton delighted in are a striking feature. There is much pleasure in such a walk, but it does not compare with, is not of the same character as, the pleasure of walking in such a garden as Batsford Park, where there is both breadth and great variety of garden pictures. Variety maintains interest and feeds the mind in a way that monotony cannot do. To compare a garden with a collection of pictures, whether would it be best to have four big pictures on the four walls of one's room or a collection of smaller pictures arranged with proper taste?

London.

W. Watson.

[A picture-gallery exists solely to show each of its individual treasures to the best advantage, and no one thinks that its contents, taken together, should also make a picture or that the paintings which it contains should be grouped or "composed" into larger pictures. Too many persons assume that a garden exists for its individual plants, in the same way that a gallery does for its individual pictures; but there certainly can be an arrangement of the contents of a garden which will give a very complete and satisfying effect, an effect entirely different from that which comes from the enjoyment of the individual flowers or plants. No objection was made by M. C. R. to variety, and no preference was expressed for a few bold groups; a plea for harmony is not an argument for monotony. The title of the article expresses its purpose. It was not aimed against Accumulation, but against Accumulation without Disposition. It is perfectly easy to have a variety of plants and yet to dispose of them so that a consistent purpose will reign throughout, and the garden will not only make a picture, but a new picture, from every point of view. Every one has seen drawing-rooms full of valuable furniture and objects of art which were ugly and wearisome because their contents were unskillfully disposed. A skilled artist might so arrange these objects that the beauty of each would be enhanced by its position and surroundings, while the effect of the whole would be pleasing. It is possible, however, to crowd a place so full of objects beautiful in themselves that no arrangement can save it from a cluttered and depressing appearance, and every one can recall the impression made by some simple room which contained nothing really precious, and yet wore an expression at once of comfort and of grace. A man may ransack the earth for vegetable curiosities and rarities, and fill his garden full of them, and yet it may be a spotty and uninteresting place to look at. It will certainly be such a place if he has been governed by the desire for accumulation alone and gives no thought to the disposition of his material.

After all, it should never be forgotten that there are gar-

dens of every size, and an infinite variety of tastes and habits to be gratified by them. And so long as one really loves his garden and finds health and comfort and delight in caring for it, he is to be congratulated, even if, to the critical eye, its pictorial effect is not satisfying.—ED.]

Salix balsamifera.

To the Editor of GARDEN AND FOREST:

Sir,—It will doubtless interest the readers of GARDEN AND FOREST to know that Salix balsamifera, Barratt, was collected in the White Mountains by the late William Boott. There is a specimen of undoubted *S. balsamifera* in the Boott Herbarium, marked in Mr. Boott's handwriting, "Salix cordata, Lake of the Clouds, Mount Washington, 12th July, 1855."

This plant, then, was collected thirty-two years after its discovery by Mr. Little, and twenty-four prior to its detection by Messrs. Pringle and Faxon.

Botanical Garden, Cambridge, Mass.

Merritt Lyndon Fernal.

Apple-scab in Nebraska.

To the Editor of GARDEN AND FOREST:

Sir,—Last season served to illustrate in a striking way the effect of climate upon fungus depredations. While the Apple-orchards of New York were so overrun by the scab fungus that the crop in many sections was almost a failure, Nebraska was so free from it that in the vicinity of Lincoln scarcely enough could be found to illustrate the effects of the disease on the fruit in lecturing to students. The early part of the season in the eastern states was marked by long-continued wet weather, particularly favorable to the development and spread of fungous diseases. In Nebraska just the reverse conditions prevailed, for the season was an unusually dry one, and at the very time when crops in the east were suffering from too much rain, crops in Nebraska were suffering for the want of it. The chief point aimed at in the spraying experiments at this station was to find whether it would be profitable to cheapen the cost by weakening the mixtures used. It is needless to say that the results were entirely negative, for all were alike useless, and the arsenites alone would have given just as good results. Of course, the present season was unusual, but, to a certain extent, the same conditions prevail every year, and fungi of all kinds are much less abundant here than in the eastern states, consequently the directions for spraying best suited to the east do not apply here. Moreover, some of the enemies which trouble eastern growers have not yet reached us. It should not be inferred from this, however, that we are altogether happy, for in the "blight," "rotten heart," etc., we have enough to occupy our attention. For the present it does not seem advisable to recommend more than two applications of the Bordeaux mixture to Apple-trees in this section, and, indeed, if this season were a fair sample, none at all would be much better.

Lincoln, Neb.

Fred W. Card.

The Forage Problem in Iowa.

To the Editor of GARDEN AND FOREST:

Sir,—The farmers of the north-west, particularly those living west of the Mississippi River, have had some valuable lessons from the dry season of 1894. They have not learned much about weeds or fungi, since diseased plants of all kinds have never been as scarce as during the months of June, July and August, and our annual weeds have suffered quite as much as the perennial grasses in meadows, lawns and pastures, and they will, therefore, be freer from these pests than they have been for many years. The season has been of particular interest, because of the opportunity afforded to study the forage problem. Many forage plants, for example, have been found wanting in their ability to stand long droughts.

The chief forage-plants of the state are Blue Grass, *Poa pratensis*; Clover, *Trifolium pratense*; incidentally also, White Clover, *Trifolium repens*. Indian Corn heretofore in this state has not been used extensively as a forage-plant, but this year it has come into prominence for this purpose. In fact, had it not been for corn, live stock could not have been carried through the months of July and August. This suggests the important fact that the farmers of Iowa have annually been wasting millions of dollars' worth of the fodder which is contained in the Maize crop. It is a well-known fact that the corn-stalk contains about fifty per cent. of the dry matter and over thirty per cent. of the protein of the plant. It is not improb-

able that hereafter Corn-fodder will be saved more largely and used in place of hay.

Blue Grass has shown itself capable of standing, in an unusual degree, the severe drought. In July very little green Blue Grass could be seen. Pastures, meadows and lawns looked bare, but with the rains of August and September they became green, the strong root-stocks of this excellent and nutritious grass spreading in all directions. Timothy has also stood up well, but it afforded less pasture than Blue Grass. Clover made a better growth and gave more hay per acre than any of the old forage-plants. In seasons of this kind it is more valuable to have a mixture of Clover, Timothy and Blue Grass than to grow them separately. The most remarkable feature of these forage-plants, especially Blue Grass, is that although but little remained in pastures, cattle and horses thrived. In other words, the grasses were practically cured in the field, and hence more nutritious than in seasons of great moisture.

Of the little-tried leguminous plants none are more promising in this state than the Cow Pea, *Dolichos Katiang*, var. *Sinensis*, and Soja Bean, *Glycine hispida*, and none are more valuable than the several hardy varieties introduced by Professor Georgeson, of Kansas. Under the most trying circumstances these plants made a large growth, and contained an abundance of fodder. Sweet Clover, *Melilotus alba*, has also been tested, while it made a rapid and good growth. It is not to be recommended because of its weedy nature and the injurious effects which may result from its use. Crimson Clover, *Trifolium incarnatum*, has been a failure. Alfalfa, *Medicago sativa*, on the right kind of soil, is a remarkable drought resister, but it has not been tried extensively.

The Polygonum Sachalinense, which has been commented on so widely as a valuable forage-plant for dry years, made an excellent growth. At no time did it show the wilting effects of the dry weather. I should not advise the extensive planting of this Knot-weed. Its deep-running root-stocks are liable to be a menace in removing it from the field. It may, however, pay to have a few acres.

From these statements it will be seen that the forage problem resolves itself into the use of several different plants, and no farmer should rely exclusively on a single plant. More and greater reliance should be placed on Corn, which, under the most unfavorable conditions, will produce good and cheap forage. Sorghum must also come to the front as a forage-plant. Soja Bean may be relied on. For fall and spring pasture Blue Grass is the best of all our Grasses. It fails, however, during the summer months, July and August. During this time Corn, Rape, Soja Bean and Cow Pea may be substituted.

Agricultural College, Ames, Iowa.

L. H. Pammel.

Recent Publications.

The Woman's Book. Dealing practically with modern conditions of home-life, self-support, educational opportunities and every-day problems. In two volumes. New York : Charles Scribner's Sons.

These large elegant volumes, with their four hundred illustrations, touch upon such a wide range of topics that it is easy to understand why so many authors were engaged in their preparation. On the intellectual side of life, such subjects as Books and Reading and the art of travel are treated by T. W. Higginson and Elizabeth Bisland, with an important chapter on the Education of Woman, by Rev. Lyman Abbott. On the practical side, P. G. Herbert and Mary Cadwallader Jones write of the various fields of useful activity which are now open to women, and W. O. Stoddard gives instruction in such details of business affairs as keeping accounts and the management of real estate. The various branches of household economy are discussed by Lilian W. Betts, while hygiene of the home and the training of children are the subjects of articles by J. W. Roosevelt, M.D., and Kate Douglas Wiggin. Besides this, we have essays on the aesthetics of dress and of house-furnishing, with the inevitable instructions in regard to behavior in polite society. Altogether, the book is as useful as it is beautiful, which is saying a good deal, as no better specimen of the bookmaker's art than this has lately appeared from the press at such a reasonable price. It is really an encyclopædia on most of the subjects in which women are interested, and it treats them in a broad way,

while a very complete index makes all its information readily available.

The special matter which brings a book like this within the scope of a notice by GARDEN AND FOREST is found in two chapters: one on Home Grounds, by Samuel Parsons, Jr., and another on Flower Gardens, by Mr. J. N. Gerard. Mr. Parsons writes in an instructive way of the good and bad features of building lots, with directions for draining, and some excellent advice about the situation of a dwelling-house and the grading of its surroundings. He next takes up the subject of planting, gives the most approved methods of arranging the lawn and of planting its borders, with lists of trees and shrubs which will be found useful, and the best way to group them. One might readily criticise his selection of trees and shrubs, but no list would satisfy every one, and his descriptions of various plants with their special adaptations will be helpful to the novice. It is not an easy thing in the space of thirty pages to give a great amount of instruction on the planning and planting of home-grounds, but the advice, so far as it goes, is sound, and it will be useful if it does no more than convince the reader that there is such a thing as a proper arrangement of home-grounds, that this is a matter worth study and inquiry, and that the preparation for it should begin at the very beginning, not only before the house is built, but before its location is decided, so that house and grounds together may be one consistent scheme.

Mr. Gerard's field is rather more restricted, and, therefore, he goes more into detail, and gives the best of counsel as to the preparation of the soil, the proper exposure of flower-beds and the selection of plants to fill them. Of the essential matters which should be borne in mind when flowers are to be cultivated for house adornment, few are neglected in this little monograph. There are paragraphs devoted to hardy herbaceous perennials, to annuals, to flowers for cutting, to climbers, to window and veranda boxes, to aquatics, and descriptions of such helps as cold frames and greenhouses, with hints on some specialties like Orchid-culture. The advice is not of that desiccated sort which gets into ordinary catalogues, but the paper is full of little out-of-the-way bits of information which throw side-lights upon the practice of gardening, and cannot help but be beneficial to any woman, or any man, for that matter, who begins in a cautious, experimental way to plant flowers to make his home attractive.

The tenth edition of the *Forest Tree-planters' Manual*, prepared by Mr. J. C. Barrett, Secretary of the Minnesota State Forestry Association, has reached us, and, like earlier editions of this work, contains a large amount of interesting information and stimulating matter. It embraces a list of the indigenous trees and shrubs of Minnesota, with remarks on their distribution in the state and their economic uses and values, with such characters as will assist in their determination. There are articles also on how to manage forest seeds, seedlings and cuttings, filled with practical suggestions, articles on entomology and forest-zoölogy, and on the economic and climatic conditions of the forests of Minnesota. Such publications as these are valuable in increasing the popular knowledge of forests and forest-planting, branches of agriculture in which Minnesota has for many years taken an active part.

The Medical Plants of Tennessee, respecting their commercial value, with an analytical key, descriptions in aid of their recognition, and notes relating to their distribution, time and mode of collection and preparation for the drug market, by Dr. A. Gattinger, of Nashville, has recently been published under the direction of T. F. B. Allison, Commissioner of Agriculture of Tennessee. This is a useful book, containing brief botanical descriptions of the economic plants of the state sufficiently full to make it possible, by the aid of the excellent analytical key, to distinguish them readily, with descriptions of their medicinal uses and commercial value.

Notes.

The Miller Raspberry, which has already been described in this journal (vol. vii., page 300), will be offered by leading nurserymen this spring. It has hitherto been grown only by commercial planters in Delaware and Maryland for the sake of its fruit, and has not been disseminated.

From a private letter dated on the last day of the year we learn that Chrysanthemums were still enlivening the gardens of Santa Barbara, California, with Roses, Violets and *Salvia splendens* still in bloom. *Cestrum aurantiacum* and *C. elegans* were also in flower; the *Libonias*, *Passiflora manicata* and *Bignonia venusta* were showing some blooms, while *Veltheimia speciosa* was just coming on with Paper White Narcissus in full bloom.

The Tree Tomato, *Solanum betaceum*, is a shrubby plant, a native of Central America, growing to a height of five or six feet with large shining leaves, fragrant flesh-colored flowers and fruit said to be as large as a duck's egg and of similar shape. It is at first purple, but gradually assumes a warm reddish color, so that the plant is really ornamental as it is grown in southern California. The plants bear the second year from the seed and the fruit ripens continuously for several months. The fruit will never be of any commercial importance, but it may be eaten raw, and when it is stewed with sugar it has a slightly subacid flavor which is very refreshing.

The forty-sixth volume of the *Garden*, which begins with the first issue of this year, is appropriately dedicated to Mr. Edward Whittall, the English merchant of Smyrna, who has enriched English and American gardens with many new and beautiful plants from the hills of Asia Minor, many of which are perfectly hardy. Among these are species and varieties of *Crocus*, *Chionodoxa*, *Cyclamen*, *Fritillaria* and *Sternbergia*. Mr. Whittall is still a young and active man, and we cordially unite with Mr. Robinson in wishing that he may live long to continue the good work of distributing plants which have for ages bloomed unseen or unappreciated in those mountain solitudes.

A bulletin which gives notes on the Strawberries grown at the Geneva Station, New York, last year, contains an illustration of four rows of a seedling raised at the station and known as No. 198. The strong, upright fruit stems and large, vigorous leaves are conspicuous. This variety was only exceeded in total yield by five others, and it was especially noted for its large production late in the season, three-fourths of the entire crop, 144 ounces on thirty-three square feet, having been picked after the third of July. This is a remarkable showing. The berries are of a good dark color and large size, but they are not of the highest quality. The extreme lateness of its season of bearing, however, ought to give this variety a special value.

We are sorry to learn that Mr. C. M. Atkinson, one of the best all-round gardeners that America has seen, has been obliged, through physical infirmity, to retire from the charge, which he has held for nearly thirty years, of the gardens and estate of Mr. John L. Gardner, of Brookline, Massachusetts. This place has long been known to lovers of horticulture for its well-grown fruits and flowers, and especially for many of those old-fashioned hard wood greenhouse-plants which are so sadly neglected in most gardens of the present day, and which Mr. Atkinson grew to perfection. His skill, however, was not limited to any single field, and he was equally successful with Azaleas, Japanese Irises, Roses, Orchids, Violets, and all sorts of greenhouse and hardy plants.

At the meeting of the directors of the various experiment stations in Washington last autumn there was exhibited the photograph of a Tomato-plant which originated in the garden of Colonel M. V. Moore, of Auburn, Alabama. The plant covered a trellis about fifteen feet square, and it was said that during the season it produced more than four hundred well-developed fruits, some single specimens of which weighed nearly a pound, the average weight being about six ounces, or a hundred and fifty pounds, say, as the entire yield during the season. The fruits were round and smooth, and they grew in clusters of from three to seven. The flesh was solid, richly flavored and finely grained. The plant has been perpetuated by cuttings, and seed of some of the largest fruits has been preserved.

A late number of the *Gardeners' Magazine* contains an excellent illustration of a fruiting branch of the Sea Buckthorn,

Hypophaë rhamnoides. In his description of the plant, Mr. George Nicholson says that few growers of trees and shrubs are acquainted with the plant, although its bright orange-colored berries set closely along the branches and remaining all winter long, make it especially valuable. The fruits are somewhat bleached by hard freezing, but in late autumn they literally glow in the bright sunlight. *Hypophaë* is hardy in our northern states, but it is less common here in cultivation even than in Great Britain; in fact, we have never seen good fruiting plants of it in America. The genus is diceous, and the staminate plants are, of course, useless for decorative purposes. That it should be better known and more generally grown must be the opinion of any one who has seen it in some Swiss valley in September, when its bright fruit makes a striking display.

The latest news from Florida shows that the orange crop will not be a total loss in some of the groves in the central part of the state and along the south-western coast. Although heavy frosts prevailed in these parts and the thermometer fell to twenty-eight degrees, there was no long-continued cold, as throughout other sections, where the freezing weather lasted for three days, and the oranges were frozen solid on the trees. Later on these oranges dropped, and the ground was thickly covered with useless fruit, and in many instances the leaves also fell, while the bark burst the entire length of the trunks. Besides the supplies of Mediterranean fruit under way to supply the deficiency, the New York market is ready to take the supply from Jamaica, Porto Rico and Cuba, so that, although there will not be as many oranges of the first quality as was expected, there will be no scarcity of fairly good fruit at reasonable prices. In ordinary seasons the shipments of oranges from Jamaica stop when the Florida season is fully under way, and this is true also of Cuba oranges. Jamaica oranges sold at auction on Saturday at \$4.50 a barrel for the best, while damaged Florida fruit could hardly be sold at any price. Mediterranean oranges are selling at wholesale for \$2.50 to \$3.00 a box. Tangerine oranges bring \$5.00 a box for a grade which brought \$2.50 a fortnight ago. Almeria grapes of good quality can be had for thirty cents a pound. Hot-house strawberries from New Jersey cost \$3.00 a pint, and hot-house pineapples from Florida may be had as low as thirty-five cents each.

Dr. Bornet has published in the *Bulletin de la Société Mycologique de France* a sympathetic notice of Philibert Picart, the French engraver, who is specially known to Americans by his engravings in Engelmann's classical work on *Cactaceæ*, and in the first volumes of Sargent's *Silva of North America*, upon which he had been exclusively engaged for several years before his death. "Philibert Picart," Professor Bornet tells us, "was born in Paris on the 2d of December, 1825. A pupil in the School of Design of the Rue de l'École de Médecine, he obtained, at the age of sixteen, the highest prize given in that establishment. Soon becoming the principal support, and then the head of a numerous family, he would have been obliged to abandon it for military service had not Louis Philippe generously come to his rescue and purchased a substitute for him from his private purse. With the assistance of his mother, who was as brave as himself, he succeeded, by persistence and self-sacrifice, in bringing up his six brothers and sisters. One of his brothers, Eugène, who was also an excellent engraver, was, until the end of his life, the assiduous assistant of Philibert, dying two years before him. The list of the great works to which Philibert Picart has contributed is a long one. *Les Quinquinas de Weddel*, the *Cactaceæ* of Engelmann, *l'Arboretum Segrezianum* of Lavallée, the Plants of the Orient of Jaubert & Spach, the *Jardin Fruiter du Muséum* of Decaisne, the *Chilian Voyage* of Gay, the *Batrachospermum* of Sirodot, the Forest Trees of North America of Sargent, are familiar to every one. A skilled entomologist, the zoologists are not less indebted to Picart than the botanists. 'An indefatigable worker,' said Monsieur Migneaux, in the sympathetic address delivered at his funeral, 'conscientious, an excellent observer, with a talent supple and ingenious, which specialists and savants, whom he aided, can alone appreciate. Picart was certainly the most complete expression of that group of engravers who have illustrated the works of natural history in the second half of this century. Among the multitude of scientific publications to which he contributed it is proper to mention as the most important, perhaps, the works on cryptogamous plants of Tulasne and Thuret. The plates of this work, engraved from drawings of Riocreux, are simply masterpieces, the like of which will, perhaps, never be seen again.' Picart possessed rare unselfishness and integrity. The man was the equal of the artist."

To Preserve the Palisades.

IN one of his journals, Thoreau, in speaking of the natural beauties of a country, declares that they have a high use which dollars and cents cannot represent. If the inhabitants of any town or state were wise they would spare no pains to preserve such beauties, for they furnish a kind of education that no hired teachers, preachers or school systems can supply. The most impressive object he found in a certain New England town was a noble Oakwood to which he felt assured that men from all parts of the country would make pilgrimages a hundred years hence if the town would only save it. But if the people there were of the same temper with the inhabitants of many other towns they would estimate the value of the grove only for what the trees would bring as timber. In many countries precious metals belong to the crown, so here more precious objects of rare beauty should belong to the public. The summit of Mount Washington was once in litigation before the New Hampshire courts, which were to decide whether it belonged to A or B. "Think of a mountain-top," he adds, "which even the Indians revered as a sacred spot, only accessible through private grounds—a temple which no man can enter without the danger of letting out or letting in somebody's cows!"

No doubt, this is fundamental truth on which Thoreau here takes his stand, but, after all, he is bringing up a form of the old and ever-recurring problem, how to reconcile the rights of the individual with the rights of society. The ocean is free to every keel, and yet there are miles along our coast-line where the people are fenced away from its beach, as if they had no right even to look at a spectacle which in all time has been a source of health and inspiration to man. Places with a history which ought to stir the pulse of patriotism have been degraded into low resorts by landowners, who prize and use their historic associations simply as an advertisement. But it is not just to denounce people as criminal for using what is their own property as may suit their advantage within the limits of the law. If any one is censured, the blame should not rest solely on the men who devastate natural beauty or places rendered

sacred by some noble action in the past. It is rather the fault of society, which has never decided what are the rights of the individual to the beauty of the world into which it has been born. One reason for this is that we do not recognize the real value of such spectacles and associations as an uplifting and civilizing force. Libraries have been written to prove the value of art as a refining influence on society, and a man would be justly considered a vandal who should destroy a priceless painting of some old master, even if it were his own private property. But vandal is a harsh word to apply to the men who are blasting down the face of the Palisades and defacing the dignified portal through which one of the noblest rivers of the world enters one of its noblest harbors, and yet no one can deny that the destruction of the Palisades would be a calamity more serious than the loss of any work of art on the continent.

We allude once more to the danger which threatens the Palisades because the Governor of New Jersey in his late message invited the attention of the Legislature to the matter, and has suggested the passage of certain acts which he thinks will prevent this magnificent natural rampart from becoming a prey to the quarryman. The purchase of the Palisades throughout their entire length as a public park Governor Werts considers out of the question on account of its expense. What gives the rock its market value, however, is its proximity to navigable water and the ease with which it can be loaded for transportation. Some of the riparian rights of the state have been disposed of, but it still practically owns two and a half miles of the shore, including those portions now utilized by the quarrymen. The Governor recommends that the riparian laws of the state be so modified that the building of stone-breakers or piers for working and loading the rock shall not be permitted on the state lands, and that none of the water-rights of the state shall be disposed of without such limitations as will make the work of quarrying unprofitable. We are by no means assured that such legislation would save the Palisades. Nevertheless, it would be well if such a law were enacted, so that a practical test of its value could be made.

Another suggestion in the message of Governor Werts is to be commended without reserve, and that is the appointment of a commission under a general act to receive and hold such lands in the state as they may deem for any reason worthy of reservation for public use. This is practically a similar commission to the one organized in Massachusetts, which we have had frequent occasion to speak of with approval. If the people of any state feel that their rights in spots which are hallowed by tradition or are inspiring by their beauty are being infringed upon, they must organize to assert these rights, and no better plan has yet been devised than this board of trustees of public Reservations in Massachusetts. There are few other states in the Union where a man who owns a battlefield or a waterfall in fee simple can give it to the public, much less sell it, because no one is entitled to hold it legally for the state. The existence of a continuous body like these trustees is a constant invitation to public-spirited citizens to make over for the public use forever many places which ought to be reserved. Governor Werts thinks that if such a commission in New Jersey could secure a few points on the Palisades besides those which would be protected under the modified riparian act the danger would be averted. Let us hope that this will prove correct.

In any event, neither New Jersey nor any other state can err in organizing a perpetual board of trustees to hold forever all places whose history or natural character justifies their reservation as public property for public use. It is a pleasure to add that, since the foregoing paragraphs were written, a bill has been introduced into the New York State Senate to create a commission for this purpose, composed of eminent citizens from different parts of the state, and that the bill expressly authorizes the commission to coöperate with similar bodies in other states, where joint action is

desirable for the preservation of such places as the Palisades.

Jean François Boursault.

EVERY one knows the Boursault Rose, of a race of hardy climbers, whose parent is the European *Rosa alpina*, although probably very few people know much of the man, once a conspicuous character in Parisian life, whose name it now best commemorates; and we are glad of the opportunity to publish some facts concerning him, for which we are indebted to our correspondent, Monsieur Edward André, of Paris.

Jean François Boursault was born in Paris in 1752, or, according to the *Dictionnaire Larousse*, toward 1760, and died in Paris in 1842. He was the great-grandson of Edme Boursault, a poet and author of some celebrity, and the son of a linen-draper in easy circumstances of the Quartier des Innocents. Boursault early left Paris to follow a band of traveling players, making for himself some reputation in his earliest rôles. Admiration for his ancestor, the dramatic author, influenced his choice of the theatrical profession, and out of respect to the memory of his name, which he did not want to run the risk of having hissed, he adopted that of Malherbe, which he retained as long as he continued on the stage. Boursault established a French theatre at Palermo, but being unfortunate and his affairs involved, he took advantage one day of King Ferdinand's passing to throw himself into the sea. This excellent method of getting his head above water, as a wit of the time remarked, succeeded admirably. A crowd collected, the curiosity of the king was excited, and Malherbe, who had been fished from the water, was brought before him. The actor described his miserable condition in such a dramatic manner that the sympathy of the king was moved and he gave him money enough to pay his debts. Returning to Paris at the beginning of the Revolution, Boursault plunged into the movement with enthusiasm, but soon afterward returned to the stage, and had built for himself in the Passage des Nourrices, between the Rue St. Martin and the Rue Quincampoix, a theatre which he called Théâtre Molière. In 1806 Boursault changed the name of his theatre, which he now called Théâtre des Variétés Étrangères, and undertook to play Shakespeare, Schiller, Lope de Vega, etc., an undertaking which soon failed. Next we find him engaged in cleaning the streets of Paris. His street-cleaning contract and the gambling-houses, which he obtained control of later, made him immensely rich, and he became known for his taste in horticulture and his collections of plants. The garden of his villa in Rue Blanche and his gallery of pictures were among the most famous in Europe. He collected in his hot-houses the rarest plants of the two hemispheres. In 1830 he bought for three millions of francs the Salle Ventadour and became director of the Opéra Comique. This venture was not successful, and he was on the point of failing, but eventually was able to save his fortune. After this, with the capriciousness of old age, Boursault sold his famous gallery, pulled down his hot-houses, which were the richest and best-stocked in France, and, perhaps, in Europe, destroyed his park, building on its site two rows of houses, which now form the Rue Boursault. This was his last fantasy and his last undertaking, for he died shortly afterward, leaving a large fortune.

Green Ash in the West.

AMONG hard-wood trees the Green Ash has been more extensively planted in the west than any other species, and the method pursued illustrates better, perhaps, than in the case of any other tree, the lack of forest knowledge on the part of planters. The Ash is a light-foliaged tree, and, though slow in growth, it requires full sunlight for its best development. Planted in solid plats, or mixed by rows with other species, it does not shade the ground

enough to prevent the growth of weeds and grass, and hence in the west the strong prairie grasses check its growth very seriously. Planted pure in this way, the trees are also apt to grow crooked, and, therefore, when they have attained useful size they are of much less value than if they had been forced to grow straight, as they do when closely surrounded by Box Elders or other good shade-makers.

The Green Ash has a wide western range, extending from the Dakotas to Texas, and following along the streams from the Missouri to the mountains. Although it prefers the deep moist soils of river-bottoms, it can be grown better on upland than many other trees, but its growth in such situations is much slower than it is in moister ground. In the forest plats of the South Dakota Agricultural College, at Brookings, Green Ash is grown more slowly than White Elm, Black Cherry, White Birch, Box Elder or the Poplars, but faster than Burr Oak and Black Walnut. Planted among Box Elders at Brookings it reaches up for the light, and there is little doubt that at ten years of age the Ash will equal, if not overtop, the Box Elder.

I was much interested in the forest-trees growing in the town of Hastings, Nebraska. In the early settlement of the country, about twenty years ago, Mr. Alexander planted a tree-claim near the town, which, in course of time, was divided into town lots, and now the best residence street of Hastings is made beautiful by these plantings. A great many Green Ash are included in this artificial grove, and so greatly do the trees vary in size and in the shape of their seeds that I was strongly of the opinion that there were both White and Green Ash in the plantation. A comparison of the seeds with that of White Ash as grown here, however, proves all the Hastings trees to be Green Ash. It indicates a very great range within the species, both as to habit of growth and form of seed, and explains the very common error, in the west, of mistaking *Fraxinus Pennsylvanica*, var. *lanceolata*, the Green Ash, for *F. Americana*, the more common eastern species.

Washington.

Charles A. Keffer.

Hybrid Oaks in Western Missouri.

NOT having given much attention to the Oaks of Jackson County, Missouri, beyond noting their geographical and geological distribution, and not having observed any hybrids, I had come to think that there were none in this part of the state. Engelmann had observed and described a number of forms from eastern Missouri and western Illinois, and had even proposed several of these as species, but they have all been enumerated as hybrids in the last edition of Gray's *Manual*. Supposing that hybrid Oaks were comparatively rare, I had not taken the trouble to watch out for them until my attention was attracted by a remarkable one, which I at first thought was the offspring of *Quercus alba* and *Q. Muhlenbergii*, and since then I have learned that these hybrids are comparatively common. Of the six hybrids mentioned below I do not recollect to have seen any one described, and they certainly are not given among those in Gray's *Manual*.

Several years ago I observed a tree which seemed to be the offspring of *Quercus alba* and *Q. macrocarpa*, near Courtney, Missouri. This was the first I had seen here. The general appearance of the tree was that of *Q. macrocarpa*, the leaves even being lyrate, but the fruit was plainly that of *Q. alba*. I gave the tree little attention at the time, and it was not until I had discovered the tree mentioned above that I thought of it as a hybrid. Three years ago I found another tree which I took to be a hybrid between *Q. alba* and *Q. Muhlenbergii*. I had sent this to Dr. Britton and Professor Trelease as *Q. alba* × *macrocarpa*, and the former wrote me that the fruit was exactly of the eastern *Q. Prinus*, but it is a clear *Q. macrocarpa* × *Muhlenbergii*, as I afterward ascertained by a critical study of the tree and the species in the neighborhood of it.

Two years ago I found what I took to be a hybrid of

Quercus alba and *Q. Muhlenbergii*, and after observing it for three successive seasons I still think it the same.

Last fall I discovered several more hybrids, and will mention those that I noticed more particularly. A hybrid *Quercus macrocarpa* × *Muhlenbergii* was found one mile east of Independence in a grove of Red and Shingle Oaks. It has the light-colored trunk and smoothish limbs of *Q. Muhlenbergii*, but some of the leaves resemble those of *Q. Muhlenbergii* and others those of *Q. macrocarpa*, while the fruit is exactly between that of *Q. macrocarpa* and of *Q. Muhlenbergii*, and has no fringe. Another hybrid was observed by myself and Rev. Cameron Mann near Sheffield, in this country, and quite a number of trees were noted. The tree appears to be *Q. macrocarpa* × *bicolor*, and they occur in a grove where *Q. bicolor* and *Q. imbricaria* were the prevailing Oaks, with no sign of *Q. macrocarpa* present. The trunks were generally light-colored, as in *Q. bicolor*, and some of the leaves were those of that species, and others were like those of *Q. macrocarpa*. The fruit was intermediate in character, but approached that of *Q. bicolor* in shape and *Q. macrocarpa* in size.

Another tree, a hybrid evidently of *Quercus rubra* and *Q. imbricaria*, was found a mile east of Independence, standing alone in a pasture, but the supposed parents were both present within a short distance. The leaves exhibit all gradations between those of *Q. rubra* and those of *Q. imbricaria*, and the fruit is intermediate between the two species, and larger than the fruit of *Q. imbricaria*.

These six hybrids are derived from six different species, and from the apparent ease with which they intermingle it is expected that there are many more in this locality.

Specimens of all but the first one of the trees noted above are deposited in the herbarium of the Missouri Botanical Garden and in the herbarium of the Arnold Arboretum.

Foreign Correspondence.

London Letter.

TALAUMAS.—Sir Joseph Hooker begins the one hundred and twenty-first volume of the *Botanical Magazine* with a figure of *Talauma Hodgsoni*, prepared from a plant which flowered for the first time in cultivation in the temperate house at Kew this summer. The species was discovered by Sir Joseph in 1848, in the eastern Himalaya, forming forests in the valleys of Sikkim, at an elevation of 6,000 feet. He describes it as "one of the noblest of the flowering forest-trees of the Himalaya, a country which, considering its narrow area, contains, perhaps, more handsome Magnoliaceous trees than does any other of equal dimensions in India, if not of the world." The handsomest of all is, of course, *Magnolia Campbellii*, which is hardy in the warmer parts of this country, and forms a big shrub in the neighborhood of Cork, and when in flower has no rival among the Magnolias grown here.

Talauma Hodgsoni was received at Kew about twenty years ago, and for a time grown in a tropical house. About seven years ago it was removed to the temperate house, where one of the plants is now a handsome tree twenty-five feet high, with leaves two feet long. In Sikkim it grows to a height of forty feet, forming a thick trunk sometimes six feet in girth. The flowers, which are produced singly on the ends of the branches, are six inches across, the fleshy sepals colored vinous purple externally, the petals white, tinged with rose at the tips. They are very fragrant and, unfortunately, very fugacious.

I noticed the flowering of this plant in one of my letters to GARDEN AND FOREST a few weeks ago, and shortly afterward received from Mr. H. Nehrling, of the Milwaukee Public Museum, a letter suggesting that as the genus *Talauma* would probably be useful for gardens in the southern United States it might be worth while calling special attention to them in these pages.

The genus is closely related to *Magnolia*, differing only

in the arrangement of the carpels and their mode of dehiscing. They are all trees or shrubs, and, so far as I know, evergreen. The flowers are generally large and very fragrant. Fifteen species are known, and in their distribution they are very remarkable, being found in South America as well as tropical and subtropical Asia, extending up to Japan. Only few of them have as yet been introduced into gardens, the oldest among those now in cultivation being *Talauma Candollei*, which first flowered at Kew in April, 1862, and has flowered there probably every year since. It is grown in the Palm-house in a pot, where it forms a leggy shrub, six feet high, with ovate dark green leaves six to ten inches long. The flowers are solitary on the ends of the branches, nodding, about six inches across when fully expanded, the sepals and petals fleshy, creamy white, changing with age to a tawny brown, and, from the time when the buds first burst to the fall of the petals, emitting a powerful and delicious pineapple-like odor, one flower being sufficient to fill the whole of the large Palm-house with a pleasing fragrance. Dr. Lindley says it can only be propagated by grafting it on *T. pumila*, but cuttings of it have been rooted at Kew. The plants grow very slow. They require stove treatment, an example tried in the temperate house at Kew having succumbed to the first low winter temperature. In Java, where *T. Condollei* is a native, it grows to a height of fifteen feet. In the *Botanical Magazine*, t. 6614, there is a figure of a smaller-flowered form which had been sent to Kew by Louis Van Houtte, the Belgian nurseryman, as *Magnolia Galleotiana*.

Talauma pumila is another Javanese species, much dwarfer and bushier than *T. Hodgsonii*, and, though smaller in flower, quite as powerfully fragrant. It has been grown at Kew many years, forming a bush two feet high, with ovate dark green leaves four inches long, and yellowish white flowers three inches across. A plant has been in the temperate house for some years, but it grows slowly there, and rarely blooms, whereas in the Palm-house it flowers annually.

Talauma Plumieri is a native of Dominica and St. Lucia, in the West Indies, but it has not yet been introduced into gardens. It forms a large tree, often eighty feet high, the wood of which is strongly scented. The leaves are ovate, four to six inches long, glabrous, with strong venation, and the flowers are as large as in *T. Hodgsoni*, white, tinged with pink, and very fragrant.

Talauma ovata was discovered in the Organ Mountains, Brazil, by Gardner in 1838. He describes it as a large tree about forty feet high, growing in swampy places, and says the powerful odor exhaled by the flowers extended more than half a mile from the tree. The flowers, which are as large as in *Magnolia conspicua*, are of a dull yellow color, and the fruit as large as a man's fist. Another name for this species is *T. fragrantissima*.

Talauma gigantifolia, a native of the Malay Peninsula, is remarkable for the size of its leaves, which are sometimes a yard long and a foot wide. It forms a large tree, the flowers being four inches across, white and very fragrant.

Talauma mutabilis, a native of Moulmein, is very similar to *T. Candollei*, and has white, very fragrant flowers.

London.

W. Watson.

When vistas are to be cut through tall-grown wood a clear idea of the effect from every view-point is essential. This can be gained at any season, but the work is most successfully done in spring; for the structure, as well as the outline, of each tree may then be distinctly seen. During some days accordingly, as the progress of vegetation is slow or rapid, scarcely any two trees are exactly of the same color; while one retains its wintry hue, another is forming colored buds, a third is in fuller bud, a fourth bursting, a fifth in pallid leaf, a sixth of a deeper tint, so that, at this critical juncture, the branches of adjoining trees may be seen distinctly, how intimately soever they may be mixed with each other; and thus the outline of either may be seen, before the other be removed.—*Planting and Rural Ornament*, 1796.

New or Little-known Plants.

Protea cynaroides.

SOME account of cultivated Proteas, with a figure of *P. nana*, one of the small species of the genus, was given in GARDEN AND FOREST, vol. iv., p. 412. The figure on p. 35 is from a photograph of a specimen of the largest-flowered species, which is grown in a sunny, dry greenhouse at Kew, along with Agaves, Aloes and other succulent plants. Here it is planted out in a bed of gravelly soil, and it is now eight feet high, with half-a-dozen stems, each an inch in diameter, clothed half-way down with bright green leathery leaves, not unlike those of a Griselinia. The flower-heads are large, the largest like the flower-heads of Artichoke, *Cynara Scolymus*, and colored bright pink. They last a long time, several months, and are very attractive, both in form and color. When I was in South Africa in 1887 I saw thousands of these plants growing wild on the sides of hills, their roots among the large stones which were thickly strewn among the gravelly soil and their stems four or five feet high. I never saw one as tall as the plants at Kew, and this is to be accounted for by the stems breaking off at the base easily if unsupported. At Kew they are supported with a stake, consequently stems which have flowered push into fresh growth at the top and flower again.

The inflorescence of Protea is composite, a large number of small flowers being aggregated in a head and surrounded by colored leaves on bracts. When the heads of *P. cynaroides* first open they are full of honey and are known to the Boers as honey-pots. This honey is collected and made into a kind of sugar. I saw large bushes of other species of Protea in the neighborhood of Grahamstown, some of them in flower, and they were quite as effective as big specimen Rhododendrons are when in bloom. They all grew in fairly exposed situations on the hill-sides, and often in positions where there was very little soil for the roots. They ripen seeds freely. Proteas would be excellent shrubs for the gardens of the southern United States. There are about sixty species of them, all African, and all sufficiently attractive in flower to be worth a place in the garden. Once they were popular in English gardens, but now they are practically unknown here.

London.

W. Watson.

Plant Notes.

RICHARDIA ELLIOTTIANA.—This Calla, as we saw it in the Temple Garden Show, in London, last spring, was a most interesting plant, with its spathe of clear rich yellow and its foliage mottled like that of *Richardia albo-maculata*. Comparatively few plants have yet been imported into this country, but last week we saw them flowering in one of the houses of Messrs. Pitcher & Manda at Short Hills, New Jersey, and our good opinion of the species was confirmed. Three years ago an account was given in our London letter of the sale of the stock of this plant at auction by Captain Elliott, who had originally raised it from seed which he had received as that of a red-spathed Calla. He increased the stock by seed and offsets until he had some two hundred and fifty plants, and he sold these at auction for more than \$2,000. The plant had already received the first prize as the best new plant in bloom at the International Horticultural Exhibition at Earl's Court, in London. It differs from the yellow-flowered *R. Pentlandii*, which is tinged with purple at the base of the spathe on the inside, and which does not have the finely mottled leaves of *R. Elliottiana*. As observed at Messrs. Pitcher & Manda's, the plant seems quite as vigorous and floriferous as the ordinary Calla, although the leaves appear somewhat more dwarf, so that the flowers stand higher above the foliage. The tuber resembles that of an ordinary Caladium, and every tubercle, if removed and carefully attended to, will grow into a flowering size in less than two years. There can be little doubt that this yellow Calla will soon

find its way into every collection of plants and every florist's establishment throughout the country.

COREOPSIS GRANDIFLORA.—An excellent colored plate of this, the best of all garden Coreopsis, is published in a recent issue of the London *Garden*, and it reminds us to repeat what we have already stated more than once, that this plant was long distributed in this country, and is now largely known in gardens here as *C. lanceolata*; that is, a better plant was sent out in the place of an inferior one, the true *C. lanceolata* being a good perennial, but not nearly as showy since the flowers are much smaller. The plant, however, is much hardier, since the crowns of *C. grandiflora* are quite often killed by New England winters if it is left outdoors. The latter is more inclined to a tufted habit, and when grown in pots for early spring decoration it is a most useful plant. The difference between the two plants is easily recognized, even in the seeds, those of *C. grandiflora* being larger and not so dark in color as those of *C. lanceolata*. The true *C. grandiflora* has been distributed as *Coreopsis "Harvest Moon,"* and will be readily recognized under this fanciful though inaccurate name. In the length of its flower-stalks, the size of its flowers and the freedom with which they are produced, *C. grandiflora* is the best of the garden Coreopsis, and its liability to winter-kill in the north is not so much of a drawback as would be expected, owing to the freedom with which young plants are produced from self-sown seed in the borders. These are harder than two-year-old plants, and live through the first winter, flower the next year, should then be replaced by self-sown plants or by some that have been protected over winter in cold frames.

CHOROZEMA VARIUM, VAR.—A correspondent writes of a seedling from a variety of Chorozema varium which seems to have a more compact habit than the parent plant, and is now covered with racemes of richly colored flowers, which are almost as large as those of a garden pea. This is much larger than these flowers usually are, but they vary much, and European nurserymen now offer garden varieties said to be much superior to the old kinds. Many of the old kinds are excellent plants, and not really difficult to manage if they are hard cut in after they have done flowering, repotted firmly and allowed abundance of air and light always. They seem to do better here in the open air during summer, so that the new growth will become thoroughly ripened. The Chorozemas are Australian hardwood shrubs, and the flowers are most of them red and yellow in different shades and mixtures. Most of the flowers are much smaller than those of the variety noted, but what they lack in size they make up in abundance, and in late winter and spring they are excellent for decorating conservatories. In southern Florida, like many other of the Australian shrubs which can endure dryness at the root for some time, they do admirably in the open air.

Cultural Department.

Peach Yellows.

PROFESSOR L. H. BAILEY, of Cornell University, has been making a careful examination of Peach orchards in western New York, where there have been complaints of the yellows, and has been publishing some notes on the subject under the direction of the State Commissioner of Agriculture. Some of his conclusions are these:

The yellows is a distinct disease, attacking the Almond, Apricot, Japanese Plum, as well as Peach, and it attacks thrifty as well as feeble trees. It has been recognized as a disease for a century; is communicable from tree to tree; is incurable, and the termination is always fatal. Its cause is wholly unknown, and no fertilization of the soil will cure it or check its spread. The one very unmistakable symptom by which it can be recognized is the red-spotted character of the fruit, the flesh being marked generally by red lines or blotches beneath the spots. These peaches generally ripen prematurely the

second year ; they afterward come smaller and more fuzzy than the normal fruit. The first symptom to appear on the trees, rather than on the fruit, is the so-called " tips," that is, the short undergrowth starting from the upper or terminal buds, usually late in the season and characterized by narrow,

limbs, and in advanced cases the shoots may branch into close bunchy tufts. In the final stage of the disease there is a small and slender growth of all new wood with small narrow yellowish leaves, and occasionally a profusion of slender branched growths in the centre of the tree. Diseased trees die generally in five or

Fig. 5.—*Protea Cynaroides*.—See page 34.

stiff, yellowish, small leaves standing out nearly at right angles from the shoot. These tips sometimes appear after the leaves have fallen in autumn, or before the normal growth begins in spring, and they are often seen upon the ends of water-sprouts. The third special symptom is the slender, stiff-leaved, yellowish shoots which come from the body of the tree, or the large

six years from the first attack, and the only known means of keeping the disease at bay is to exterminate the affected trees, root and branch. The disease is communicated to nursery stock by affected buds and by buds from branches of affected trees which do not yet show signs of the disease. Pits from affected trees may also be expected to propagate the disease.

Seed-sowing.

If a greenhouse is available this is the best possible time to sow seeds of herbaceous plants that were not sown in the fall when gathered. An ordinary greenhouse temperature is most suitable—that is, a temperature such as is required for Carnations, of fifty degrees at night, with a corresponding rise during the daytime with sun-heat. When first sown, the seeds should be covered with some non-conducting material, as a thick sheet of paper. Chopped moss is advocated by some growers, and this answers well enough if it is known about what time the young plants will appear. But if, as often happens, the seeds are slow in germinating, it is not well to use the moss. If the seeds are covered with glass it must be turned each day to get rid of the superfluous moisture, or they will decay. We never use glass except for very small seeds, to avoid too frequent watering and the consequent washing out of the soil that sometimes takes place even from spraying. All the smaller seeds should be placed by themselves, so that they can have special care and attention. Small seeds are often sown too deep, and so fail to germinate. A safe rule is to cover them with a depth of soil equal to the size of the seeds. A suitable soil is one composed of equal parts of loam and leaf-mold, with plenty of sand to make it porous, and, if it is possible to obtain charcoal-dust, this is beneficial, but this is not easily obtained now. When Japanese Lily-bulbs were exported in this material it was more generally used, and proved of great value in all potting soils. Any one who has charcoal-dust for sale would do the gardening public a kindness by making the fact known.

Seeds of hardy plants especially are best sown thinly over the surface. Seedlings which are thickly crowded are necessarily weak, and if decay does not set in in the seed-box it is likely to attack them after they are transplanted. A heavy watering followed by a dull day is often the cause of great mortality and disappointment.

Seeds sown now will make strong plants by April, when they can be hardened off in a frame, and later on planted in the open ground. By sowing seeds of herbaceous plants now this work will be out of the way before the seeds of garden annuals require to be sown, a real advantage where many annuals have to be sown each year.

E. O. Orpet.

The Newer Chrysanthemums.

ON page 18 of the current volume of GARDEN AND FOREST Mr. J. N. Gerard comments on the newer varieties of Chrysanthemums as compared with the older kinds, and adds that little attention has been given to the raising of such varieties as will bloom in the open garden. In part this is true, and in part it is misleading. For many years much attention has been given by European growers to early-flowering varieties that will bloom to advantage, and thus make attractive outdoor plants. These are known as the Madame Desgranges (*syn. G. Wermig*) type, and in Europe they have been found to be a useful class of plants. Messrs. Peter Henderson & Co. enumerate a large number of the more recent early-flowering varieties in their catalogue of last year, and doubtless there are many other growers in this country who devote considerable space to them. But, so far, they are an unsatisfactory group in our climate. The hot days and cold nights of our autumn months can hardly be called favorable to their best development, and hence, to insure a crop of good flowers, they must be grown under glass, like the later-blooming kinds.

A great deal is said about the beauty of those old-fashioned varieties that will survive a few degrees of frost. As a matter of fact, most of the modern varieties placed in commerce before 1890—I have not seen the later sorts tested—will live and bloom through similar hardships. It is believed by many persons that the flowers of such plants, old as well as new, are still exquisite when in reality they are seriously disfigured by eight or ten degrees of frost, and I never could see any great beauty in a bloom one-half of whose florets had been blackened by the cold. There are, of course, various contrivances by which plants out-of-doors may be protected from early frosts; but in the case of a plant so indisputably tender as the Chrysanthemum, it seems to me that the expense of a greenhouse would be slight in comparison with the constant trouble and worry in watching the barometer and in placing and removing the protecting material. Many plants of a far harder nature than the Chrysanthemum, such as the Hellebores, for instance, have their beauty much marred by exposure to the elements, and, judged alike from the standpoints of pleasure and expense, I know that it pays to place a cold frame or a greenhouse over such plants.

Peter the Great has been cited as a very desirable variety, and with many others of a bygone generation it deserves commendation. It is one of those good old varieties which have endured the test of time, but which are now being crowded out by the newcomers. Many considerations prompt us to plead for these veterans; they have done yeoman service in the past, and we must feel sympathy for their past triumphs. But their day is over, and the laurels must now go to the newer, and, it must be admitted, the better races. Peter the Great, as I remember it, bore magnificent blooms. But as I have seen it in recent years it is quite as good, so that it is the advance of other kinds, and not the deterioration of this one, that has left it in the rear. The habit of Peter the Great, like that of many old varieties, was ungainly, and to obtain flowers from them of good size and quality it was and, with all our improvements in methods of culture, is still necessary to grow the plants with stems from six to eight, and even nine, feet high. Compare this with many of our modern American varieties, producing blooms of the greatest excellence on stout stems from three to four feet high, and clad with luxuriant foliage almost to the base of the flower.

It may be said that these fine single heads are not the true test of the value of a Chrysanthemum. But when the new varieties will not only endure this test, but will equal or excel the older ones when judged by any other standard, it will be seen that there is little besides sentiment to justify the cultivation of the good old sorts. No doubt, flowers are worth growing for sentiment alone, and if so, let it be admitted frankly. This is certainly better than to claim for old favorites a grace or beauty which they do not possess.

Cornell University.

M. Barker.

Primula Sinensis.

THESE plants are in good form now and will continue to make a fine show for months to come. For the decoration of a cool greenhouse they are indispensable during the winter months, while the double varieties are very useful for cut flowers. The best time for sowing seeds is the end of March or the beginning of April, and a very suitable soil for the seed is equal parts of loam, leaf-mold, with sand to cover the seeds lightly. Heat and moisture is what the seeds need until they have germinated, after which they should be gradually exposed to light and air to prevent them becoming drawn, to which they have a tendency during all periods of their growth. They should be potted singly into small pots when large enough to handle; the soil should be finely sifted and have a little dry, well-rotted cow-manure added. They should never be allowed to become pot-bound, as it causes premature flowering, which greatly retards the growth of the plants. For the final shift six-inch pots are quite large enough, and good specimens can be grown in five-inch pots.

A cold frame in as cool a position as possible suits them best during the summer months; the roots, especially, must be kept cool, which is best done by plunging the pots in ashes or half-rotted leaves, they may be shaded from strong sun, but should have abundance of light and air to keep them strong and bushy. All flower-buds should be pinched off as they appear until about the middle of October, which is also a good time to get them into winter quarters. After flowering commences, occasional applications of liquid-manure is very beneficial, but this must always be applied in a weak state.

The double varieties are hard to procure from seed and are generally propagated by divisions. This is best done by removing a few of the bottom leaves and plunging the plants well down into a bed of leaf-mold and sand, where they will make fresh roots from the bare part of the stem and can be divided into single crowns and potted up separately.

Tarrytown, N. Y.

William Scott.

Celeriac.—Almost every one who relishes celery will like this vegetable quite well, and yet it is rarely seen in country gardens, although it would seem that everything which adds variety to the home table would be tried. The edible part of this turnip-rooted Celery, as it is popularly called, is the root, although the top can be blanched and used, but this is stronger in flavor than celery and not as crisp. The seed should be sown in a flat and covered lightly, and if paper or glass is laid over it any sunny window will be a good position for it, although where there is a greenhouse this is the best place. The covering should be removed before the plants become drawn, and they should be transplanted when an inch high into other boxes two inches apart, where they may remain until they are set into the ground the first of May. The rows should be two feet and a half apart, and the plants may be set nine inches apart in the row. The roots will be large enough to eat early

in September. They can remain in the ground, however, and will continue to increase until heavy frosts about the first of November, when they should be brought into a light cellar where the temperature never descends to the freezing point. If they are set on the ground close together and watered well, the roots will take hold and keep them fresh. Celeriac is good in soups and dressings, and makes a delightful salad when boiled and sliced.

New York.

Lilium elegans.—This Lily, with its various forms or varieties, makes one of the best groups of the whole genus. All of them will thrive in ordinary garden soil, with less care than most species. With me the bulbs take hold the first year and seem quite free from decay. *L. elegans* is a native of Japan, and, thus far, has proved hardy here. The bulbs increase in size so that moderately small ones, if well fed the first year, become large by the second autumn. The price, too, is much in their favor for general use, as most of its varieties can be had at reasonable rates. There are, however, so many forms and synonyms for this group, that one is lost in making a selection from some of the lists. One house in Europe offers no less than thirty-four forms under various names and prices, which, no doubt, might better be reduced to ten or twelve. One variety, called *Elegans semiflore-pleno*, is a half-double form, while there is recently offered, among novelties from Japan, a double-flowered variety called *Elegans flore-pleno*. *L. Thunbergi*, *L. umbellatum* and *L. Batemannii*, together with their sub-forms, all belong to this species. The variety *Alice Wilson* is said to be one of the best, but unfortunately the price is still quite high. Although there are prominent distinctions between many of the forms of this Lily, such as shades of color, height, time of flowering, etc., yet, of the five or six which have been tried here, there is little difference so far as their disposition to thrive with common care. Even in dampish ground, where only such kinds as the *L. superbum*, *L. tenuifolium* or *L. tigrinum* would be expected to prosper, these forms of *L. elegans* have increased and bloomed.

Carnations in Flatbush.

To the Editor of GARDEN AND FOREST :

Sir,—Among the most extensive growers of Carnations for the New York market are Messrs. Dailedouze Brothers, of Flatbush, Long Island, who have 36,000 feet of glass. In connection with Carnations, they grow a strain of large-flowering Mignonette, which they have established by long continued selection until it is quite distinct, although unnamed. A week ago, when ordinary Mignonette was bringing \$3.00 to \$4.00 for a hundred spikes in New York city, this stock commanded \$10.00 to \$12.00 for seconds. The choicest heads at the same time brought \$3.00 a dozen at wholesale, and the largest trusses were sold by them just before Christmas for as much as \$6.00 a dozen, a price said to be higher than has ever before been realized for Mignonette. These selected spikes were ten inches long, with a good diameter, and were very compact. The stems are stiff and the foliage heavy and flowers close.

The seed is sown about the first of September in solid beds, and in rather heavy soil. The plants are thinned out after they show four good leaves, which is about five weeks after the time of sowing. They are tied up and watered sufficiently often to keep them moist. After they start to flower, liquid stimulant is applied once in two weeks, chemical mixtures, cow and sheep manure and other fertilizers being used in turn, since Mignonette likes a change of food. Strong plants bear six to eight spikes each. The seed is gathered about the 15th of April, the best plants being saved for seed.

Carnations are, however, the main crop here at this time. In houses devoted to the older sorts are long stretches of the variety William Scott, which is considered here the best all-around pink Carnation for commercial purposes. It grows strong and produces freely large pure pink flowers with crisp petals. The later-flowering Madame Diaz Albertini, with its strong clove fragrance, also bears large flowers of good color, the outer petals being a lighter pink than the rest of the flower. Emily Pierson, originated by A. N. Pierson, of Cromwell, Connecticut, is here a good scarlet; it is late, not being ready to cut until after the holidays, but is better than Portia, being a continuous bloomer, with larger flowers and stiffer stems.

The yellow Bouton d'Or, which originated in France in 1889, has been tested in this country without much success and has been given up by most growers. Under the hands of Messrs. Dailedouze, however, it grows strongly and blooms freely

for a yellow Carnation, and is the only variety of this color which flowers abundantly enough to make it a commercial success. It is just beginning to furnish flowers for cutting. They are a good clear yellow in color, with carmine markings on the edge and through the middle of the petals.

Daybreak proves a good standard commercial variety, and has been cut since last fall. It is healthy, with good stem and calyx and of large size, and has good keeping qualities. The fragrant Tidal Wave is considered the best carmine, and has done well for ten years. It has been in bloom since the middle of September. Lizzie McGowan is esteemed the best white. The flowers need to remain long to develop and mature, and ten days from the time they open is not too long to leave them on the plant.

The newer Carnations included Annie Pixley, originated by Albert M. Herr, and sent out last year. It is a tall grower, a good rosy pink of solid color, and is of medium size. Helen Keller grows to extra-large size, and brings the highest price of any Carnations grown. It is considered by the Messrs. Dailedouze to be the best variegated Carnation. Adalina Kresken, sent out in 1894 by Peter Herb, has been a disappointment, the calyx bursting badly. The pink Nicholson does not do well here, and seems to need a lighter soil. Sweet Briar, sometimes called the Sleeping Beauty, resembles Annie Pixley, but is a deeper pink. It stands up well here, although a mile to the south, on lighter soil, it "sleeps" badly. The color is a good pink. Jacqueminot is a glowing bright crimson, sent out by Fisher & Sons. It is small, a fairly good bloomer, and has a good stem. The new white, Uncle John, is a failure here. It lacks constitution and is subject to rust. The Stuart, which took the gold medal in Indianapolis a year ago, is inconstant, too many of the flowers being streaked and poor in form. The few perfect ones are a fine scarlet, with a rich metallic lustre. This variety is not likely to become a standard.

The cuttings of Carnations are made in March, and are planted out the first week in May. In September they are planted in the benches, and the flowers come in salable quantity about the 15th of October. First varieties ready to cut are William Scott, Daybreak, Portia and Lizzie McGowan. Among the latest are Emily Pierson and Madame Diaz Albertini. The earliest cutting varieties, with Tidal Wave, are the most continuous in flowering.

Brooklyn, N. Y.

M. B. C.

Orchids at Short Hills, New Jersey.

To the Editor of GARDEN AND FOREST :

Sir,—This is not the season of the most profuse bloom in Orchid-houses, but flowers are never lacking at the United States Nurseries, and just now a large house filled with plants of *Cattleya Trianae* produces as pleasing an effect of soft colors as one would wish to see. I have no idea how many thousands of plants there are here, but every bulb and leaf seem to rejoice in perfect health, while the flowers are of the largest size and of the richest color. *C. Trianae* is one of the commonest and most popular of Orchids, but there is a wide difference between plants of the best varieties which have been treated to the most intelligent cultivation on the one hand, and the ordinary run of the plants which are allowed to bloom as they will, on the other. I never saw together so many plants of this *Cattleya* which were really of such high quality. Of course, there were some large specimen plants, one of them showing fifty flowers, but the charm of the collection did not come from these conspicuous individuals, but rather from the unusual health and vigor of the entire lot. The firm is cutting these flowers every day by the hundred, and they often have more orders than they can fill. For choice flowers they have realized at wholesale as much as fifty dollars a hundred, which, perhaps, means nearly twice as much at retail, when the expenses and inevitable losses are taken into account. Mr. Pitcher finds that it pays him well to sell Orchid-flowers in connection with the business of selling plants. The demand for them seems to be strong and unflagging, and I saw letters from as far west as St. Paul, and even from Denver, acknowledging the receipt of large consignments of *Cattleya*-flowers in excellent condition. *C. Percivaliana* is just passing out of bloom, but the flowers, although they are smaller than those of *C. Trianae*, have brought good prices, since they come when few other Orchids can be found in the flower market. After the season of *C. Trianae* is over, *C. Mossiae*, with which another house is filled, *C. gigas* and *C. Mendelli* and others will keep up the succession. Many of these plants are showing buds and are making larger and better pseudo-bulbs than they originally grew in their native habitat.

One of the most interesting of the group of Orchid-houses

was a long lean-to against the north side of the brick wall of another house. This house in the rear is really an excavation, so much below the level of the house against which it is built that the sun in the winter never shines upon the plants. The earth has been allowed to remain at its original level under the bench on the south side, so as to bring the moist surface close to the plants, and to serve a similar purpose a tank of water extends under the whole length of the bench on the north side, and above this tank there is continuous ventilation. The wall on the south side is really one side of a long cistern in the adjoining house. This also helps to keep the place cool and moist in summer, so that it is pronounced by experts an ideal house for *Odontoglossums*. It is one hundred and thirty feet long, and it is filled with plants of *Odontoglossum crispum*, which cover the benches and hang from the roof to the number of six or seven thousand. Of course, these are not yet fairly in bloom, although a few sprays have been cut, but the thriftiness of the plants and the strong shoots, which were covered with buds, gave promise of an extraordinary exhibition in four or five weeks. These flowers will all be sold, and retailers will pay for the sprays according to the number of flowers on them at the rate of forty or fifty cents for each single flower.

Cypripediums continue, as of old, a great specialty here, and all of the standard varieties are grown in great numbers. But besides these and all the choicer varieties, there are three or four thousand seedlings coming on in all stages of development, from tiny plants which are just visible above the moss to others in full flower. Among the new varieties in bloom I noted *C. Sallieri Roeblingii*, a cross between *C. insigne* *Amesianum* and *C. villosum*, which shows a fine flower with a wide white margin on a rich chocolate dorsal sepal. *C. Hebe purpureum* is distinguished by its midrib of deep purple suffused with rose. *Alcides* is another fine plant, the offspring of *C. hirtissimum* and *C. insigne*. Near the seedlings is another house showy with masses of *Laelia anceps* and *L. albida* in flower, and it contained a magnificent variety of *Vanda coerulea* in flower. When compared with another variety near it the great spike, which carried something like twenty flowers, seemed to belong to another species. The flowers are larger in every way, the sepals and petals are broader, and the color was a much purer blue.

A run through the houses on the hillside and the group of twenty on the plain below shows considerable change in the character of the stock from what it was a year or two ago. Many of the specimen Palms and Tree-ferns still make the centre house as shady as a tropical forest; but, as a rule, the collection is less miscellaneous than it once was, and there is a tendency to grow in quantities plants of standard varieties which are used by florists. Of course, there are novelties and rarities and specimen plants, so that the searcher for these things will find what he wants, but they are not so conspicuous a feature of the establishment as they once were, Mr. Pitcher having the idea that, owing to the limited number of amateurs who make collections of choice specimens, this part of the business can more easily be overdone than the growing of Palms, Ferns, Araucarias, Dracænas and other plants which form the staple of the florist's general stock. There is no lack of interest, however, in this part of the establishment, and many visitors would probably consider the houses filled from end to end with well-grown plants of *Adiantum Farleyense* worth going a journey to see. Certainly, no other plant can equal this Fern for massing, so as to produce effects of almost cloud-like lightness.

New York.

R.

Shall we have an Orchid Society?

To the Editor of GARDEN AND FOREST:

Sir.—Cypripediums are grown more frequently in American collections than any other members of the Orchid family, and they bid fair to become as popular for decorative purposes here as they are in Europe. Their flowers show great variety in form and color, and have lasting qualities that are unequalled. Some Orchids are favorites at once, but the taste for Cypripediums seems to be an acquired one, and one that usually comes after experience with other Orchids. Nevertheless, they are already so popular, and the raising of seedlings has become so general, that questions of nomenclature have become important. If the present ratio of increase here in new varieties continues long, we certainly ought to have some authority recognized on this side of the Atlantic as competent to give certificates of merit and stability of names to such seedlings or hybrids as are worthy of perpetuating.

It seems to be unfair that our growers should be compelled to send material for such judgment to Kew, not only on ac-

count of the delay, but because of the difficulty in getting the material there in good condition. If we had an Orchid Society established here its certificates would add value to new plants raised here and give authority for naming them. Our growers of seedlings and hybridizers sometimes feel that they do not receive due credit for their work, and this would not be the case if such work were passed upon by a society of recognized rank, whose proceedings would be published, copied and spread abroad over all the civilized world. We should know little of the work done by amateur and professional cultivators in Europe were it not for the societies which give awards for this work, and these awards are, as a matter of course, published in horticultural periodicals. It seems evident that an Orchid Society here would do, to a certain extent, for American growers what similar organizations in Europe are doing for the producers of new and improved varieties in Cypripediums and other Orchids in Old World gardens.

South Lancaster, Mass.

The Forest.

The Consumption of Wood in the Comstock Mines.

IN no other group of mines in the world have such large quantities of timber and wood for fuel been used as in those on the Comstock lode. The Hon. William Alvord, of San Francisco, California, prepared a paper on the consumption of timber and wood in these mines for the meeting of the American Forestry Association in 1891, but the paper has never been published. The facts are so interesting, however, that we have asked Mr. Alvord to allow us to use such portions of it as would be most interesting to our readers.

The walls, ore bodies and, generally speaking, the entire formation of this lode are remarkable for want of firmness and tenacity. The friable nature of the ore, which renders its mining comparatively easy without blasting, except to fracture large masses, has a counter disadvantage in requiring an expensive and complete system of timbering in order to make its extraction safe. Again, some of the mines of this lode are, or have been, operated at a depth considerably exceeding 3,000 feet. However, the chief reason for using large quantities of timber is the great width of veins carrying high-grade ore. On the 1550 level of the Consolidated Virginia mine a vein 330 feet wide has been worked out clean, and in it and various other mines of the lode, veins ranging from 65 to 200 feet wide have been worked out in the same manner. The ore of the vein in the Consolidated Virginia, above referred to, furnished an average yield of \$126.00 in silver and gold to the ton. Such ore is too valuable to be utilized for chamber-walls as principal supports, as is done in most of the mines of the world.

The enormous pressure resulting from the weight of the overlying formation, augmented by the absence of the usual chamber-walls as principal supports, is sustained by an elaborate network of costly timbering, which has been admired for its completeness, safety and structural strength by many of the most skillful mining engineers of the civilized world. Without vast quantities of massive timbers to keep the walls in place, and corresponding quantities of wood to generate power for pumping out the water, hoisting the ores, reducing and amalgamating them and retorting at the mills, the great bulk of the precious metals which the Comstock mines have poured into the lap of nations would never have been discovered, and its extraction would have been practically impossible. The constant requisitions of the Comstock mines upon the mountain-forests have led to the christening of the lode as "The Tomb of the Sierras."

When the mines of the Comstock lode were discovered the surrounding mountains were sparsely covered with a growth of scrubby Pines, *Pinus edulis*, commonly known as the Piñon or Nut Pine, interspersed with a stunted variety of Red Cedar, *Juniperus Virginiana*. These woods were the most valuable of all for fuel, being hard, resinous and fine-grained, but were worthless for timbers and lumber, being too small. They supplied the wants of the mines during the prospecting and surface-mining eras and as long as fuel only was wanted, but as soon as any considerable depth was reached the supply was entirely exhausted, and the most easily accessible forests of the eastern slope of the Sierra Nevada were encroached upon, and ever since then the forest-line of these mountains has been pushed westward before the axe, until now it is west of the eastern crest of the Sierra range and almost on a line parallel

with the western shore of Lake Tahoe, and fairly within the limits of the state of California.

Timbers, lumber and wood have been chiefly supplied in late years to the Comstock mines from the southern portion of the Lake Tahoe basin, on the California side of the state line. The wood and logs are first transported about twelve miles by rail to the lake-shore at Bijou, the railroad extending over piles 1,700 feet out into the lake to a depth of water where the steamers and barges can moor alongside of the track. The wood is unloaded from the cars on barges, which have a carrying capacity of from 75 to 140 cords each. The logs are dumped from the cars into the lake and enclosed in boom-timbers, forming immense rafts, and then towed by powerful steamers to the eastern shore of the lake. At this point the logs are sawed into timbers and lumber, which, with the fire-wood, are reloaded on cars and transported up a long incline to the summit over another railroad about ten miles long. At the summit it is unloaded and is conveyed through a flume about twelve miles to the wood and lumber yards at Carson City, Nevada, and from there it is taken by rail twenty miles to the mines, making a total distance of sixty-five miles from the forest, over two rugged mountain chains. From the forest to the mines the timber, lumber and wood are necessarily handled thirteen times, but the arrangements are so methodical and complete that the whole system is operated with mechanical regularity and precision. The flume is V-shaped, with a carrying capacity of 600 cords of wood a day, and it will transport the heaviest mining timbers as well as lumber and cord-wood.

To the present time 120,000 acres of the Sierra Nevada's choicest forests around Lake Tahoe and 75,000 acres around the headwaters of the Carson River have been denuded to operate the mines. This area was practically all heavily timbered, and when it is considered that it equals an expanse of land three hundred and five miles long by one mile wide it will be apprehended that there is good reason for calling the Comstock "The Tomb of the Sierras."

From January 1st, 1880, to January 1st, 1891, 249,756,000 feet of timber and lumber were shipped to and used in and about the Comstock mines. During the same period, 100,776,440 cubic feet of wood were consumed, and to the latter amount should be added 11,264,000 cubic feet consumed by the Carson River mills, auxiliary to the mines, making a total of 875,316 cords. For the decade commencing January 1st, 1870, and ending January 1st, 1880, the timber, lumber and wood used cannot be ascertained with exactness, but a conservative estimate by men most familiar with the facts fixes the figures at 425,000,000 feet of timber and lumber and 268,800,000 cubic feet of wood, to which should be added 10,240,000 cubic feet used in and about Carson River mills.

A moderate estimate of the average price paid at the mines for timber and lumber since 1870 is twenty-three dollars a thousand feet and for wood ten dollars a cord, so that the Comstock mines since 1870 have used wood and timber to the total value of \$46,072,548.

The consumption of forest-products by the mines for the period between the discovery of the Comstock lode and 1870 can hardly be approximated, as there are no data for that time obtainable, but \$55,000,000 is probably a moderate estimate of the entire cost of timbers, lumber and wood used in and about the Comstock mines from the date of their discovery until the present time.

The seemingly endless labyrinths of timbers in the Comstock mines, when ignited and beyond control, make a subterranean fire which burns and smolders for years. Many lives have been lost in the mines by reason of these fires, but none are recorded as having been lost because of any inherent defect in the timbers or system of timbering. The size of the timbers used varies from the huge pieces sixteen inches square and twenty-four feet long, to the smaller pieces eight inches square, used in cribbing. The species used are chiefly Yellow Pine, *Pinus ponderosa*, Fir, *Picea magnifica*, and Cedar, *Thuya gigantea*, of which the latter is found in such small quantities as to be hardly worth considering. Fully two-thirds of the whole amount used is yellow pine, about one-third fir, and less than one per cent. is cedar. Yellow pine is a favorite timber with mine carpenters on account of its exactitude in joining. Cedar is inferior to no known timber, not even excepting Redwood, for its lasting qualities underground. Yellow pine has been taken from the lower levels of these mines so compacted by the enormous pressure it has withstood as to have a density and weight exceeding those of *Lignum-vitæ*, and has been made into paper-weights and other beautiful ornaments. None of the timbers in the Comstock mines have yet badly decayed, and their life there cannot be accurately determined. The heat and vapors of the

mines surcharged with mineral atoms appear to have a decidedly preservative effect upon the timbers.

The area upon which the forest has been cut off to supply the mines is now growing up, principally in Pine, but the second growth is so slow that it will require many years for it to attain a size sufficient for mining timber. The new growth is very thick, and on some of the lower slopes of the mountains where it is over twenty years old there are few trees ten inches in diameter, and the average diameter will not exceed six inches. In the Tahoe basin, which has been cut over principally within the last ten years, the young trees are about five feet high and will average about four inches in diameter. In the Sierra Nevada Fir predominates on the north slopes where the snow remains the longest and the sun shines the least. On the other slopes Pine largely predominates.

The Book of the Rose. By Rev. A. Foster-Melliar, M.A. Macmillan & Co., New York. 1894.

This title seems rather too ambitious in view of the fact that only certain classes of Roses are treated, and their cultivation for but a single purpose is described. The author does not consider the Rose as a decorative plant, its value, in his view, consisting solely in the perfection of its individual flowers. The single-flowered species are, therefore, dismissed with scant attention, since no one ever won a silver cup at a Rose-show with an individual flower of a single Rose. Half a dozen lines are given to *Rosa rugosa*, and one line to our Prairie Rose, *R. setigera*, which the author calls the Bramble-leaved Rose. This, and many others which he does not name, he declares have only a botanical interest, making no mention of so good a plant as *R. Wichuraiana* or of *R. lutea*, besides many other useful single Roses. The Sweetbrier, so long celebrated in English poetry, has secured brief mention, chiefly because Lord Penzance has been hybridizing the plant with the view of getting some double-flowered varieties, and the author is forced to grieve because these efforts have been only partially successful, semi-double varieties alone having been obtained. From all this it will be seen that the book is prepared chiefly for enthusiasts who cultivate Roses for the purpose of securing exhibition flowers, and for such specialists it will afford the keenest pleasure.

The book opens with the usual chapters on the history and classification of the Rose, which tell nothing particularly new, and these are followed by notes on soil and situation, laying out of beds, fertilizing, pruning, stocks, propagating, etc., with directions which are mostly adapted to the English climate, and are, therefore, not very useful to Americans. Nor will American readers find much assistance in the chapter on Roses under Glass, because our own growers excel their English brethren in this matter, although it is by no means possible to raise such beautiful roses here in the open air as can be done in England. The chapter on Exhibiting is most interesting. We can hardly expect that Rose-shows will be such important events in this country as they have been in England; nevertheless one cannot but admire the wonderful care and pains which are taken in order to present the individual flowers, if not exactly at their best, at least in such a condition that they will be considered best by the judges who have an ideal of their own. We are told how to remove the buds, and which buds are to be chosen, if we are to secure the coveted prize; why different treatment should be accorded to different varieties in order to prevent some flowers from becoming too coarse or too full, or from being too long in opening; why some varieties should only have one bud on a single stem, and what precaution should be taken in such cases to prevent malformation; how "protectors" should be prepared and when they should be removed; why and when the buds should be shaded; how to paper and dress them, and how to exercise generalship and legitimate maneuvering for the last hour before the judges enter—all this is told with great skill and knowledge, and is certainly very amusing, and is instructive, too, in

showing what can be done to make a flower perfect, according to any given standard, by persistent and intelligent care.

The part of the book which will be of the greatest use to American readers, however, is the chapter entitled *Manners and Customs*, which, in a thorough way, makes mention of the peculiarities of habit, general appearance and behavior, under different circumstances, of the best-known varieties. The list is not complete like the admirable one in Mr. Ellwanger's book, but the descriptions of the varieties which are named are much more minute, and all the drawbacks, as well as the good qualities of the show-varieties, are noted. The demerits and bad habits of each are pointed out just as their good qualities are, and besides the peculiar ways which mark different groups or families, the "manners" of individual varieties are set forth so thoroughly that one feels sure that the author is familiarly acquainted with all of them and that he writes out of abundant personal experience. The book is illustrated with several half-tone plates, and many of them really help the text. They are not as well executed as American half-tone work usually is, although some of them show admirably the texture of the leaf and the shading of the petal. Perhaps the judge of an English Rose-show would like the prize plant whose illustration fronts page 181, and certainly it shows the highest cultural skill. Persons who prefer Chrysanthemums tied and staked into a perfectly globular form, and with flowers appearing at equal distances all over the surface, will probably like this Rose much better than one naturally grown. The reverend author tells us that it will often take a man three days to tie and wire one of these big plants into the shape of a pyramid, globe or cone. Sometimes they are trained with a flat back and without any growth on that side, and these one-sided plants, according to the author, look well where the pots are stood up against the wall.

Notes.

Mr. J. H. Hale writes to the *Florists' Exchange* that a single nursery company in Georgia has planted a hundred bushels of native chestnuts, which are now in nursery rows simply to produce seedling stock upon which to graft cions of Burbank's new Sweet Chestnut. The company has contracted to propagate a half a million trees.

At a recent exhibition in Holland, Mr. J. H. Schober exhibited fruiting branches of fifty-two species of Conifers grown in his pinetum at Schovenhorst (Patten), on ground which less than fifty years ago was a barren moor. In a catalogue of the Pinetum Schoberianum, published in 1892, one hundred and ninety-nine species and varieties of coniferous plants are enumerated.

Professor Webster, of the Ohio Experiment Station, has been making experiments to determine whether honey-bees are injured by spraying fruit-trees with the arsenites while they are in bloom. These tests seem to show conclusively that bees are killed in this way. Apart from the destruction of the bees and the consequent loss to the apiarist, this would seem to be a bad policy for the fruit-grower, since the presence of bees is acknowledged to be of great value in securing a crop of fruit by their work in pollinating the flowers.

No species of Orchid as important as the beautiful *Cypripedium Charlesworthii* was introduced in quantity during the year 1894, but one new genus has been described, coming from the Andes, and forty new species. Two remarkable natural hybrids have appeared, with many striking varieties of natural hybrids already known. The *Orchid Review* gives a list of between fifty and sixty hybrids which are considered sufficiently important to put on record as having flowers for the first time during the year, and, of course, there are many more which can in no way be considered as improvements on existing varieties.

Unlike bananas, which are usually eaten as a dessert fruit, plantains, as is well known, are unpalatable unless roasted or boiled. It is not generally known, however, that the inner undeveloped leaves and the flower-buds of the Plantain are often boiled and eaten like cabbage and made into a curry. A palatable drink is made by covering crushed ripe bananas or

plantains with water and allowing the mixture to stand for a few days until it ferments. Since Bananas and Plantains are singularly free from diseases, there is, no doubt, a promising future for their cultivation, as the uses of both for various purposes are largely on the increase. Bananas are now preserved, canned and dried, and both bananas and plantains, when dried and ground, make a meal which is highly palatable and nutritious.

A leguminous evergreen climber, with flowers a foot across, whose petals are pure white, of a tissue-like texture, with a narrow fringe on the edges like gold lace, would certainly present a magnificent spectacle when in full bloom. On page 103 of our last volume, *Camoënsia maxima*, a tropical African climber, was described by Mr. Watson as bearing such flowers, and although the plant is not new, and many large specimens are found in European glass-houses, it was said that no one as yet had succeeded in flowering it. It was stated also that a plant sent from Kew to Ceylon ten years ago was now flowering with great vigor in the famous botanical gardens of that island, and it has also flowered in the botanical gardens of Trinidad. From the *Kew Bulletin* we now learn that Mr. W. Mackie, gardener to Mrs. Ruddle, of Tewkesbury, England, has at last flowered the plant successfully. No doubt, as its habits become better known these beautiful flowers will be seen more frequently. It has been suggested with great probability that the plant loves bright sunlight and a good deal of it, so that one would think it a promising subject for some of the large collections in this country.

The established fact that leguminous plants are able to gather a portion of the nitrogen they need for food, either directly or indirectly, from the free nitrogen of the air, suggests that it may be worth while to investigate the foraging powers of different plants for other nutrients. Every one knows that in any given soil different plants are grown with different degrees of success, and it seems quite likely that some plants are able to use certain compounds of potash or phosphoric acid in the soil which are not so readily available to others, just as leguminous plants can obtain nitrogen from sources that are not available to the Grasses. Some tests were made at the Maine Experiment Station last year to ascertain the capability of different plants to appropriate phosphoric acid, and they seem to indicate that Wheat, Barley, Corn, Peas, and especially Turnips, can secure this food from crude, finely ground South Carolina rock with greater or less ease, while Beans and Potatoes derive no benefit from it. Of course, definite conclusions can hardly be drawn from one year's work, but these investigations are being continued. It would be a distinct gain to horticulture and agriculture if it could be known in what particular form each particular plant preferred to have its food.

Owing to the unexampled destruction in Florida from the late freezing weather half-rates were allowed to shippers by transportation companies until the 16th of January, so that seventeen and a half cents covered the freight on a box of oranges from Jacksonville to New York. This low charge induced large shipments, and whereas but 12,000 boxes of Florida oranges reached New York during the first week after the crop had been frozen, nearly 60,000 boxes arrived last week. Prices have ranged from fifteen cents to \$1.00 a box for frosted fruit, \$5.00 being asked for choice oranges gathered before the frost. Grape-fruit seems to have been more severely injured even than oranges and has been selling slowly at the nominal price of fifty to seventy-five cents a box, while Tangerine oranges seem to be the least affected and sell at \$1.50 to \$2.00. Jamaica oranges now command \$5.50 to \$6.00 a barrel at the steamer's side. Havana Strawberry pineapples range from \$3.00 to \$12.00 a hundred, and Aspinwall bananas cost \$1.12½ a bunch by the truck-load. English hot-house grapes have advanced in price with the scarcity of Almeria and other sorts, and Gros Colmans bring \$3.50 a pound. Large Easter Beurre pears cost \$1.00 a dozen. The highest grade of cranberries is quoted at the unusual price of \$14.00 a barrel, retail dealers asking twenty cents a quart. Florida cucumbers, cauliflower, chicory, egg-plants, peas and string beans, which a month ago were in regular supply, have been cut short by the frost, and the standard winter vegetables will have to be depended upon for some weeks to come. Some tomatoes from as far south as Key West bring thirty cents a pound for the best, and tomatoes from Cuba cost the same price. Other vegetables now coming from Cuba are onions, okra and peppers, and small supplies of well-blanch'd Romaine lettuce are now imported from Bermuda. Bermuda potatoes cost \$7.50 a barrel, and cabbage from Denmark \$6.00 a hundred.

Legislation against Plant Pests.

In the month of May, 1894, a resolution was passed by the Legislature of Massachusetts requesting the Representatives and Senators from that state in Congress to use their influence in securing from the Federal Government an appropriation of \$100,000 to assist the commonwealth of Massachusetts in exterminating the gypsy moth. A committee appointed by the Massachusetts Board of Agriculture has visited Washington in pursuance of this resolution, and, as we understand it, the matter is now regularly before the Congress of the United States. Really, this is not a new movement, for the effort to secure this appropriation is simply a renewal of what was tried last year. There is little probability, however, that any action will be taken in this matter at the national capital, although that section of the Constitution which authorizes Congress "to provide for the common defense and general welfare of the United States" has often been interpreted with great liberality. We can all remember when Congress authorized agents of the Department of Agriculture to enter upon private premises and slaughter animals which were adjudged to have pleuro-pneumonia, and then paid the owner what they pleased. The general welfare seemed to demand that our herds should be guarded against this danger, and, as a matter of fact, pleuro-pneumonia was utterly stamped out.

Few persons now believe, however, that it is practicable to exterminate the gypsy moth. The state commission, which has been fighting it, have undoubtedly done much to prevent its spread and have narrowed the territory over which it once extended. But this moth is so prolific and so indifferent as to what it feeds upon that its actual extinction, now that it has gained a foothold, seems out of the question. It may be true that if the insect is allowed to multiply unchecked it will overspread a large portion of the country, and in this way prove a national calamity, but the machinery for restraining it has now been so thoroughly organized that a comparatively small force of men employed as watchers in districts that have not been entirely cleared can control and gradually lessen its ravages. The western states will not be inclined to spend money to protect themselves from a danger so remote, and will probably suggest that Massachusetts should take care of her own insects.

This is certainly a wholesome rule. In this particular instance it may be a special hardship for Massachusetts, but there are many other insects quite as destructive, and there are fungous diseases even more serious, and if this state or other states should once discover that national aid was easy to obtain they would do nothing for themselves, but trust to general welfare appropriations altogether.

It will never answer, on the other hand, to make light of the dangers and damage which come from insects, fungi and other foes of agriculture and horticulture as not worth considering by legislatures, state and national. If, as it has been estimated, this damage amounts in the country to half a billion dollars a year, or say a million and a half of money every day, there are few subjects of greater economic importance. It must be admitted, too, that these losses can in no way be checked without coöperation of some kind, and organized effort usually comes in the form of law. It is worse than discouraging for a man to spend time and money in ridding his Apple orchards of the tent caterpillar, or his Plum-trees of the black knot, when his neighbor allows both insect and fungus to multiply on trees on adjacent land. It does not seem unreasonable, then, in cases for which there are known remedies, that landholders should be held responsible for their own premises, and that when these premises are allowed to become hot-beds of pestilence and breeding-grounds of injurious insects, the representatives of the people should step in and clean out these plague spots at the expense of their owner. Laws which authorize the destruction of Peach-trees affected by the yellows have already been passed in Michigan, Delaware, New York and California, and in New Jersey the officers of the state experiment station are empowered to enter on lands where plants are infested with any new fungus and destroy the same by fire or otherwise as they shall deem best. In one of the north-western states a law was passed to compel farmers to plow over lands where the Rocky Mountain locusts had laid their eggs, to prevent injury the following year, and it provided for having this work done by the state where the landowners neglected it.

In fact, it is not difficult to draft laws to protect every careful farmer and fruit-grower from noxious insects and diseases which are bred on the grounds of careless neighbors. The trouble is that the public sentiment behind these laws is not, in many cases, sufficiently active and vigilant to enforce them. So far as we know, the law in New Jersey, which was aimed at a new Cranberry fungus, has never been put into execution. Almost every state has a statute against permitting the Canada Thistle to go to seed, and yet how many persons have ever been prosecuted for such negligence? The very classes most interested in the extermination of the Peach yellows and the black knot have often combined to defeat legal action, and the farmers whose lands were plowed over to destroy the locusts prosecuted the state officers for trespass. Nevertheless, just as fast as communities are educated up to the enforcement of them, such laws ought to be enacted. Everybody in eastern Massachusetts, for example, ought to know the tent caterpillar and the cankerworm, and ought to realize what their unchecked ravages mean. It would seem that the time has come in some states, at least, when public opinion ought to be sufficiently strong to enforce a law compelling every man to keep his land cleared of these pests. Other insects will doubtless prove quite as injurious at some future time, and, therefore, such a law may well be broadened out to give the state entomologist authority to warn landholders of the importation of any new insect, or of the appearance in alarming numbers of any that are well known.

One difficulty is that people do not know their foes when they arrive. The gypsy moth itself would not have gone on increasing for several years before it was discovered unless it had started in a region where the cankerworm defoliated every year a large portion of the trees, and the inhabitants had become

so accustomed to seeing injuries of this sort that they never thought of examining one of the marauders to see what it looked like. Pear-trees have been dying for half a dozen years in Essex and Union counties, New Jersey, and it was not until last year that one out of the scores of men who saw their orchards wasting away thought of sending one of the destructive borers to the experiment station to be identified. The wood leopard moth must have been ravaging the shade-trees of the city of New York, Jersey City and Newark for years before the year 1887, when the first specimen was accidentally found in a spider's web, and yet there are more collectors of insects in this one region than in any other portion of the United States. The story of the pear midge and the red-necked blackberry borer has been told in these columns more than once, and we have given examples of other insects and diseases whose ravages at the first could have been arrested by the prompt action of some one in authority, but which have gone on conquering without check until they are almost hopelessly beyond control.

Experience has amply shown that many of the most disastrous outbreaks of our insect enemies could have been easily quelled at the outset. To meet such emergencies it is necessary that the machinery for repressing them should always be ready. There should not only be enactments authorizing constituted authorities to enter the field at once, but means and penalties should be provided to insure the enforcement of the law. As the knowledge of insects and their ways is necessarily limited, these means of precaution and suppression should be always in the charge of skilled entomologists. More than all, every known method of popular education should be employed through the press, through farmers' institutes, through the agricultural colleges and experiment stations, and through the public schools, if need be, to instruct the people as to the magnitude of the loss which these enemies to plants may cause, so that the officers whose duty it is to act will have the moral support of the entire community.

An Old Bridge and a Long-lapsed Thoroughfare in Massachusetts.

NOT long ago a Boston paper contained an account of the old Indian trail which led between Boston and Plymouth, and which was, for a considerable period, the thoroughfare between the capitals of the two leading New England colonies. This old trail traverses from one border to the other Boston's fine Franklin Park, and for a considerable distance its course may still be traced, though the improvement of the park has, to a certain extent, obliterated it. The claim that this old path is the Indian trail to Plymouth evidently rests upon traditions in the families who have owned land in this neighborhood from the period of the first settlement, and it is undoubtedly very good evidence, as far as it goes.

These early trails and roads are a very interesting feature of many eastern towns, and should be, for that matter, of western towns as well. Many of them, of course, have developed into modern thoroughfares, and have thus lost their interest as relics of the past. In many cases, however, the exigencies of modern traffic have caused the construction of entirely new roads, and left the old thoroughfares to lapse, first into cart-roads and then into footpaths, and at last, no doubt, to be almost totally obliterated by up-springing woods. But it is astonishing how long an old road may be traced through the woods, even after every sign of human interest in it has been lost.

In the old town of Wrentham, Massachusetts—a place saturated with traditions of King Philip's war, and where the stump of an old Oak is pointed out as the tree in which the famous Indian chieftain successfully concealed himself when the whites were pursuing him—there is a beautiful and most interesting old stone bridge which now serves to carry across Mill Brook a path leading from a dwelling-house to a spring. No road whatever now crosses this

solid old arch; but the path which goes over it bears many signs of having once been a thoroughfare. It leads from a locality now called Glenwood, where there is a lonely shoddy-mill, to a locally famous ledge called Indian Rock. Here there is very good evidence that a band of thirty Indians who had participated in the Medfield massacre were waylaid and slain by the whites during Philip's war.

The old bridge is shown in the accompanying illustration (see page 43), and is from a photograph taken in the summer of 1894 by Miss Helen Chamberlin. It is built wholly of a slate-like stone, which now possesses a beautiful purplish tint. It has a covering of turf; it is almost completely overgrown with a luxuriant mass of mingled Poison Ivy and Virginia Creeper, and the stream beneath it, which just above issues from Whiting Pond to join the Charles several miles lower down, is here choked with all manner of water-plants. The region about it is an utterly wild one—scarcely tamed at all by the shabby and solitary little shoddy-mill which stands near. No one about the neighborhood seems to know the history of the bridge. It is certainly extremely old; it must have taken a great deal of toil to build it; and manifestly it once carried a thoroughfare over the little river.

Gardening a Good Outlet for American Vitality.

IT is sometimes asked why there is so much more interest taken by the English clergy and country gentlemen in gardening than is manifested by the corresponding class in the United States. Why is it that in our country parishes we do not find that enthusiasm which has given us so many charming books about gardens from reverend gentlemen in England who have rendered practical service to floriculture? It was to the experiments of the Honorable and Reverend William Herbert, in 1836, that we owe some of our earliest knowledge in hybridization. Indeed, his efforts were so coolly received by contemporary botanists that he complains that their answer to his curious specimens was "we do not thank you for your mules." We have an attractive picture of Sydney Smith working to beautify the grounds about his various forlorn rectories. And who does not relish his practical joke in honor of a coming guest, for whom he made the parody of a park in his domain by tying oranges to the glossy leaved shrubs in the garden, and fastening horns to the two donkeys peacefully grazing on his tiny lawn that they might play the part of deer?

The Reverend Charles Kingsley made quite a little paradise out of a damp and most unpromising situation at Eversley. He drained ponds, and planted and beautified; turned a wretched chicken-yard into a grassy court bordered with flower-beds, and trained Roses, scarlet Honeysuckles and Virginia Creepers to climb over the wall between the house and stables. His borders were always gay with Phloxes, Larkspurs, Pinks, Pansies, Roses and Carnations, and his rare trees and blossoming vines afforded him great delight, and transformed a neglected spot into a charming garden. We all know how enthusiastically Dean Hole has worked to interest the British public in flower-shows, and what his single efforts have done for the development of floriculture all over England; and these well-known names are only a few among many who have taken, and still take, the keenest interest in this beautiful pursuit, and find in it their solace and delight.

Of course, the English rector or vicar has a peace of spirit from the permanence of his position which the American clergyman, dependent upon his popularity with an exigent congregation, cannot enjoy. The calm superiority of district visiting is quite another thing from the weary social duties of a country parson in a Yankee village; but there must be something besides this to explain why more ministers here do not put their spare time into their gardens, and so gain at once health and enjoyment by wholesome labor.

The climate, of course, goes for a great deal, for Eng-

land's damp, mild atmosphere keeps one, perforce, upon the go, and apparently there are few months in the year when a man cannot work comfortably in his garden and find something to reward his efforts. There roses are to be found until Christmas, unnipped by frost, and Thorns are known to bloom in midwinter. Mrs. Boyle, in *Days and Hours in a Garden*, tells how she cut a long spray, all wreathed in pearly bloom, on New Year's Eve from the Glastonbury Thorn at Marston Bigot, in Somersetshire. In that mild climate Daisies bloom in January, and Hepaticas and Violets are found on warm and mossy banks. Primroses, apparently, never fade in Mrs. Boyle's garden, and Iris ensata ventures to appear in February. Daffodils take the winds of March with beauty, but are preceded by the Snowdrop, the Crocus and the Polyanthus, and accompanied by the Kerria-buds and pink tints upon the Peach-trees.

Such things are rare with us so early, north of Washington, and one can realize how under such circumstances the garden in England becomes a constant wooer which ever encourages and recompenses its votaries.

In England the rich man enjoys his garden, plans it, expresses himself in it. Agriculture and forestry are a part of his business in life. He is, and must be, a husbandman in a large sense, must understand the details of his estate, and give personal consent to the cutting of timber. Here the wealthy owner of a place often takes no more interest in it than in the sidewalk in front of his town house. A glance shows him that it is clean and well swept, and that is all he wants to know. The detail is left to the gardener, and his ideas, not those of the proprietor, are expressed in the grounds. The effect of this is that a man's culture, his fine taste, his trained critical perception go for nothing in his surroundings, and a general dead level of uniformity ensues, with a few notable exceptions where some one takes the matter into his own hands and produces a definite and interesting result which bears the traces of thought and individual experience.

It would be a good thing for us if the country gentleman could be revived with his traditional interest in his lands and crops; and it is possible that the new impulse to re-

Fig. 6.—An Old Bridge in Wrentham, Massachusetts.—See page 42.

There is another reason, too, why folk walk abroad in the little island more than they do here, which has been noted by Mr. Edward Freeman in the *Fortnightly Review*, and Mr. Price Collier recently in the *Forum*. The American loves reading more than the Englishman, and the garden finds a rival in the library. Both these writers note that while there are more profound scholars in England, the "general reader" exists in far greater numbers on this side of the Atlantic. The Yankee is nothing if not well smattered, and his newspapers are a day's work in themselves. Moreover, his head is apt to be full of all manner of things which conflict with the serene pleasures of digging and weeding. Business, politics, all sorts of duties, intervene; he spends his life in one perpetual strain, driven by the whirling temperament within him; by the maddening climate without; by the infinite unrest of a seething civilization which boils about him, and by that impulse to get ahead which tethers him to an office desk, and is at once his glory and his shame.

main late in the country is an evidence that the tide is setting that way, and that the coming century, among its other developments, will witness a growth in personal interest in country places. Every one who has once tasted the real delights of gardening returns to it with zest. Tranquilly pursued it gives a certain richness to life and thought, a wholesome basis for intellectual labor. It is a common bond between the wise and the ignorant, a pursuit wherein men of different station can interchange rôles and mutually impart knowledge. Rivalry here is of the friendliest; the cottager's Rose may surpass that of a duke, and the interest of one in his specimen be as keen as that of the other.

If there is one more noticeable fact than another about Americans it is the lack of deep root in the soil. We have not the strong local attachment which comes with a long family history connected with a family estate. Everybody goes west, or somewhere else, instead of maturing on the ancestral acres, so that home is not so much a spot to grow fast to as to move away from, and no one builds gardens

for strangers who are soon to occupy his place. Nevertheless, the remarkable increase in the culture and sale of plants during the last fifteen years is an unmistakable evidence that we are a plant-loving people; but so far the development is more among nurserymen and florists than in individual interest of home-makers. That is, it goes more by fashion than by personal taste, but many important movements have grown out of fashions, and the proprietor who buys because his neighbor does, gradually comes to look with interest upon his plantations and flower-beds, and in time will come to know something about them and to derive benefit from them.

Beyond any question, a more general devotion to gardening among Americans would help them to lead lives of greater serenity and sanity. They could afford to read fewer books and newspapers if they only learned these lessons of peace which come from contact with nature. It would be a solace to poor and rich. It would cultivate the taste and gratify the love of beauty in many a home where costly works of art are not to be thought of. And is it not also true that the wholesome recreation in the open air would be especially beneficial to the men and women who are devoted to literary work? To return to the clergy once more, would it not be wise for them to take a leaf from the book of their British brethren for their own enjoyment and health, as well as for the effect upon their sermons. There is no better outlet for nervous irritability produced by brain work than out-of-door struggles with reluctant nature and her six-footed armies. If we are to have a vigorous literature we must have hearty men behind it; therefore it is to be hoped that the literary man of the future will feel himself not fully equipped for his profession unless he be the owner of a few square feet of garden soil from which he may derive mental vigor with bodily wholesomeness.

Hingham, Mass.

Plant Notes.

FONTANESIA FORTUNEI.—Mr. John Dunbar, the Superintendent of Highland Park, Rochester, New York, calls our attention to the fact that *Fontanesia Fortunei* is hardy and a desirable ornamental shrub in Rochester if it is carefully mulched in winter. It is a plant of the Olive family, with slender graceful branches covered with deep green leaves, which do not fall until late in the season. The greenish or creamy yellow flowers, which are crowded in the axils of the leaves, are interesting rather than conspicuous. *F. Fortunei*, which was introduced from China a few years ago, is only known there in the neighborhood of Shanghai, where it is often planted in hedges. Botanists now consider this plant identical with *F. phyllyreoides* of the Mediterranean Basin and Asia Minor, and it has been suggested that it had been introduced into China from southern Europe or the Levant. Mr. Dunbar, however, finds that *F. phyllyreoides* grows less freely and does not flower in Rochester.

NARCISSUS BULBOCODIUM MONOPHYLLUS.—This delightful little Hoop-petticoat Daffodil was brought into English gardens more than twenty years ago, but was for a long time rare in cultivation, and was supposed to be difficult to manage. It is a native of Algeria, where it is found in great abundance, and if the bulbs are kept dry and baked in full sunshine all summer as they are at home, they need no other special attention. It is said that newly imported bulbs flower in England in December, but here, at least, after a year's cultivation, this is the natural season of flowering, and Mr. Gerard now has these Daffodils in full beauty in a cool house, where they have grown without any forcing. The delicate flowers are snowy white, with orange-colored anthers, and a panful of the plants in full bloom makes a very pretty show. The corona is bell-shaped, and it has the small perianth sections peculiar to the species. The flowers have a fragrance which is even heavier than that of the Paper-white Narcissus, and which is not pleasing to

every one. A figure of the plant is to be found in vol. v., page 211. Professor Foster has raised an interesting and pretty hybrid between *N. triandrus* and this plant, which is said to combine the charm of both of its parents, with a sturdier constitution than the variety *monophyllus*. The flower-scapes of this new plant, which he named *Narcissus Trimoni*, by combining the first syllables of the specific names of its parents, are nine inches long, usually two-flowered, each flower being two inches across. The whole flower is milk-white.

BRODIEA (TRITELEIA) UNIFLORA.—Although this little bulbous plant comes from Argentina, it is hardy in our eastern states, and it bears in late spring single star-shaped flowers on slender stalks above the narrow leaves, which are about one-eighth of an inch wide and six inches long. If the bulbs are planted in the grass and the foliage is not cut until it ripens, the plants will bloom freely year after year in the sod, where the delicate lilac-colored flowers are seen to the best advantage. There is a pure white variety which is quite as hardy and more beautiful. We mention the plant now, however, on account of its value for flowering in pots in winter, for it can easily be had at this season, and the flowers last a long time. The bulbs should be planted in September, and need nothing beyond ordinary treatment, that is, good soil, free drainage and liberal water when growing. A dozen bulbs can be planted to advantage in a six-inch pot set in a cool, shaded frame, with fresh air every day and protection from severe frost. They can be brought into a sunny greenhouse as needed, and will develop rapidly and bloom in about two weeks. After flowering they should have a complete rest, that is, they should be totally deprived of water, dried off and repotted in the fall. Or they may remain in the same pot or pan several years if a top-dressing is given every autumn. There is an objectionable garlic odor to this plant when any part of it is bruised, but the flowers themselves have a faint fragrance which is not unpleasant.

New or Little-known Plants.

A Monstrous Form of the Black Spruce.

THE most curious, and certainly not the most beautiful of all conifers found in gardens is that form of the Norway Spruce, with long whip-like branches, usually called *Picea monstrosa*, and occasionally found in collections of these trees, always exciting much interest and astonishment.

Three years ago a variety of the native Black Spruce, *Picea Mariana*, of the same character was discovered by Mr. George Walker on his "Forest Dale" farm, near Williams-town, at the north-eastern base of Mount Hopkins, and 1,175 feet above the level of the ocean, about three miles from the north-western corner of Massachusetts, and one mile east of the New York boundary. When first noticed by Mr. Walker the tree was about five feet high to the top of the leading shoot, and is now eight and a half or nine feet high, its average annual growth being ten to eleven inches. The side branches are horizontal and prostrate on the ground, while the upper ones have a tendency to twine around the central stem. The peculiar habit of this tree is interesting as showing remarkable seminal variation in a tree which has been considered less inclined to vary than the Old World *Picea excelsa*, and is well shown in our illustration on page 45 of this issue, made from a photograph for which we are indebted to the courtesy of Mr. Alexander Walker, of Williamstown. Like other seedling varieties of conifers, Mr. Walker's Spruce can, of course, be propagated by grafting the ends of the branches on to seedling Spruce-trees; and it is sure to find its way into cultivation, when it will make a good companion to the numerous varieties of the Norway Spruce which delight the lovers of such plants.

Cultural Department.

A few Good Shrubs of the Hardest Type.

OWNERS of gardens in central and southern New England and New York, and other regions with corresponding conditions of climate, enjoy the advantage of being able to

winter, sheltered and peculiarly favorable localities are sometimes found where certain plants will grow satisfactorily which will not endure in most positions in the surrounding country. So many costly experiments have been made by private individuals that we now have a fair idea of the powers of endurance of most of the trees and shrubs generally known in cultivation. Exotic ornamental shrubbery has received less

Fig. 7.—A Monstrous Form of the Black Spruce.—See page 44.

grow a much larger variety of fruit and ornamental trees and shrubs with less trouble than is possible in cold exposures farther north and in higher altitudes, and especially in the cold dry regions of the north-west. Here and there throughout the colder regions, where the mercury occasionally falls to twenty-five or thirty or more degrees below zero of Fahrenheit every

attention than most other branches, but within a few years a much wider interest has been shown in this class of plants, and the work of testing and disseminating them has been fostered by some of the agricultural experiment stations. In future we may see some other shrubs as well known and commonly planted about bleak farm-houses as the common Lilac,

which now seems so much a part of the country that few people ever think of it as an exotic. It is a universal favorite, and its success is due quite as much to its easy propagation, thorough hardiness and general take-care-of-itself character as for its beautiful flowers. The plants requiring the least attention and care are the ones which will survive in the average farmer's garden. Grown from cuttings, and so on their own roots, some of the improved varieties should become popular, as they are apparently quite as hardy as the old forms. Tartarian Honeysuckles, *Lonicera Tartarica*, of several variations are extremely hardy, and the common Snowball, or sterile form of *Viburnum Opulus*, endures cold winters without protection, and is, therefore, popular. These three kinds of plants and a few Roses are the best known in many districts where nurseries are rare and variety is limited. But to these could be added many more which are thoroughly hardy in most trying situations, which are easily propagated, and which require little care after being once well started.

It should not be forgotten that some of the native local shrubs are among the hardest, and are often quite as beautiful or useful as any of similar kinds that might be purchased. Among these natives are Roses, Spiræas, Honeysuckles, Viburnums, etc. Among enduring foreign shrubs for bleak and exposed situations the *Caragana*, or Siberian Pea-trees, take foremost rank. They may be propagated with great facility by seeds. *Caragana arborescens* is the largest, sometimes growing fifteen or twenty feet high. In the Russian steppes it is said to be greatly used for hedges and screens in the most exposed places. Several other species of *Caragana* are equally hardy, but none of them grow so large as *C. arborescens*, and none are more valuable, although the persistent spiny leaf-stalks of such species as *C. spinosa* make them curious objects and suggest their value as low hedge plants. All have clear, yellow-colored pea-shaped flowers. Almost equally hardy, and much more showy, are the Mock-oranges, or species of *Philadelphus*, by a great many people called "Syringa." They are not so common as the Lilac, although the plant propagates itself very freely by seeds. Although the Mock-oranges are very hardy, their close allies, the Deutzias, are not able to stand in the same situations without suffering much injury.

The great-flowered *Hydrangea paniculata grandiflora* is valuable for its great hardiness and is likely to do well in many parts of the north-western plains, where few showy shrubs thrive.

Rosa rugosa, both the white and pink flowered varieties, is now well known for its extraordinary endurance, and it represents the hardest of its class in cultivation. It will stand without protection where almost all other kinds will fail, and from its cultivation and improvement we must look for the Roses which will take the place of present garden varieties for planting in those parts of the country where the climate is most severe.

Arnold Arboretum.

J. G. Jack.

Vegetable Garden Notes.

THE winter thus far has been a comparatively mild one; the temperature has not on a single occasion fallen to zero here, and there has been but little snow. It is somewhat unusual to see plowing, digging and planting operations in this section during the first week of January, but the ground was quite free from frost and in fairly good working order at that time. Although we prefer to manure and dig over in the fall all soil in which vegetables are to be planted, we never are able to complete this work for want of time. During dry frosty weather we had manure wheeled on ground still to be turned over, and deposited in good-sized heaps. When open weather sets in this manure can easily be spread, and there is then no necessity for wheeling through the soft ground with the barrow-wheels half-buried.

It is unlikely that any suitable weather for outdoor work will occur for six weeks. As soon as this change comes any necessary draining ought to be attended to. If drainage has been neglected in the formation of the garden, as is very often the case, no time should be lost in seeing to it. A regular plan of all drains should be kept, and any alterations or additions accurately noted. This will prevent much confusion at any time when it may be thought necessary to alter or repair the drains. Garden-tools of all kinds should be cleaned and repaired. Attention to these matters in season will save both time and expense when the tools are needed for use. Nothing so much shows the want of system on a place as an ill-kept tool-house, and yet this often looks like a useless lumber-shed. Gardeners should see that every man under their charge on quitting his daily work carries such tools as he has been using to the tool-house, cleans them properly, and puts them

in place. There is no more slovenly habit than for a workman to lay down his tools coated with manure or earth, and a man who is neglectful of these minor duties will never make a neat gardener. At this season it is well to look over the cellar or storehouse where onions, potatoes and other vegetables are kept, and remove decaying roots. Potatoes will probably need to have some sprouts rubbed off if they have been stored in an overwarm place. Celery, whether in cellars, frames or the open ground, should not be neglected. Air should be admitted on every favorable opportunity to prevent the spreading of mold. Celery has not kept as well as usual here this season. The heavy snowfall early in November and subsequent frosts destroyed many thousands of good plants. Much of the crop was frozen solid, and even such as had been earthed up had the tips badly nipped. The kinds which have kept best with us are Kalamazoo and Giant Paschal, the first named being the most satisfactory.

We usually make our first hot-bed for Lettuce early in January, and from this we get good heads in six weeks' time. We have had no difficulty in providing a supply of lettuce throughout the winter by attending to the frames carefully, and making a hot-bed once a fortnight. A gentle bottom-heat is all that is required, and we mix stable-manure and leaves in about equal proportions for the beds. If at all dry, the manure should be watered and the whole tramped down firmly. When properly made, a hot-bed will maintain a gentle heat for a long time. Too often a quantity of rank straw-manure is thrown into a frame and not mixed or shaken up at all; the result is a violent heat for a few days, which will burn the roots of any unfortunate plants which may chance to be planted over it. For forcing purposes we find White Tennis-ball still the most reliable Lettuce. Radishes of the turnip-rooted class, if sown or pricked in between the Lettuce rows, will come along very quickly. If no hot-bed is at command and a supply of Radishes is desired, excellent ones may be had by pricking them off into boxes of rich compost and placing them on a shelf in the greenhouse. Sowings of Beet and Lettuce should now be made, to be transferred to a gentle hot-bed when large enough to handle. Cauliflower and Cabbage ought also to be started in a cold house without delay, and a few small pots of Parsley ought not to be omitted. About the middle of February we sow a batch of Golden Self-blanching Celery for an early supply; there is always a likelihood of a percentage of these early-sown plants running to seed, more particularly if the plants suffer from lack of moisture at the root. If extra-sized Onions are desired, this is a good time to make a sowing of Giant Rocca, Silver King or Prizetaker; by pricking these outdoors, bulbs can be obtained double the size of those sown in the ordinary way. All varieties of Onions, by being pricked out, can be grown larger, and some growers now treat their whole crop in this way. As a general rule, however, medium-sized roots are more desirable than the larger ones.

Where a good bottom-heat is at command a few Cucumbers may be started; it is, however, unwise to sow these for a few weeks to come, unless a strong steady moist heat can be maintained. A sowing of Tomatoes made now will give ripe fruit about the end of May. Those sown in November are now in six-inch pots and almost ready to be transferred to their fruiting pots. Plants which commenced to ripen early in November are still full of ripe fruit, with plenty coming on. Periodical surface-dressings and applications of liquid-manure to plants in fruit should not be neglected, and artificial pollination must be attended to if a good set of the fruit is desired.

Cold frames containing Lettuce, Parsley, Cauliflower or any other plants require picking over occasionally, and all old and decaying leaves be removed. Snow must not be allowed to lie on the frames, except during severe weather, air and light being essential to the making of sturdy plants.

Propagation of Chrysanthemums.

A NOTHER season's work among Chrysanthemums is now beginning. Our stock has been stored in a cool, light place just long enough to develop good stocky cuttings, and after looking over the lists of novelties we shall decide which kinds to grow during the coming season. The time to propagate depends upon the use for which the plants are intended, and, to some extent, upon the facilities at command. If we have all the conveniences of heated glass structures, and intend growing large specimen plants, we should commence to propagate now. Those who are less fortunate in the matter of conveniences may wait until spring, and still have time to grow neat specimens, which are really more serviceable for general decorative purposes.

English growers propagate much earlier than is necessary

here, beginning as early as November with some varieties which are intended for specimen flowers. Their plan, however, is somewhat different from ours, as they allow a break of two or three stems, each bearing one bloom. This, with different conditions of climate, accounts for the longer season required. Generally the finest specimen plants they grow are those which have carried three blooms the preceding season. The plants grown and exhibited by Mr. Brooks at the Centenary Festival of the Chrysanthemum Society at the Royal Aquarium were of this kind, commonly called cut-backs, meaning that the old stems had been cut back to within a foot or less of the soil, and allowed only to break from the stem, and not from the root-stock. Very little advantage is gained by following this plan here; under changed conditions of climate we can grow as large plants in eight months as they do in ten months in England.

Although cuttings will root at a temperature very little above the freezing-point, it is better to use a little bottom-heat when this is possible, since it insures quicker rooting and saves time. Select the strongest shoots—suckers if possible—and prepare them with a sharp knife, shearing off a few leaves at the tips, which are liable to hang around the base of the cuttings and encourage damping. Water freely, even to saturation, for the first few days, for on no account should the cuttings be allowed to wilt, and use shading only when the sun shines. The cuttings should be rooted in about three weeks, when they may be potted into small pots, using a light soil at this stage of their growth.

For specimen blooms the first of May is early enough to make cuttings for the first batch, and all that we need do now is to keep our stock as sturdy as possible until then. If the stock is in cold frames now, so much the better, but it would not be advisable at this season to place it in such frigid quarters. If already started into growth, they had better be kept quietly moving, and be topped early in March, and a new crop of cuttings may be made about the first of May.

Ivory and Joseph H. White are still the best early white varieties for specimens, and Minnie Wanamaker and White Cap for late. President Hyde and Mrs. Walter Baker are excellent early yellow varieties, and W. H. Lincoln the best medium to late, and probably the best all-around yellow variety now known. Good reds are yet scarce, and it is difficult to excel Cullingfordii when it is well grown. G. W. Childs makes a very fine specimen. For pinks we have a good selection. Portia was the most admired of all last season. Duchess of Connaught is of a fine lavender shade. The original Louis Boehmer is superior to any of the so-called improved varieties of this flower.

Wellesley, Mass.

T. D. H.

A Few Plants that like Shade.

AMONG the hardy perennial plants that thrive in shady situations, especially under deciduous trees, are many sorts which produce the earliest flowers in spring. A conspicuous group among these are the Trilliums. Although some of them continue until midsummer, their first growth is made while they receive considerable light and warmth from the sun, before the trees have come into full leaf. The Dog-tooth Violets are another class. Our yellow Adder's-tongue, the most common of this group, is one of the earliest wild flowers in spring. The Chionodoxas (Glory of the Snow) succeed well under the shade of deciduous trees. This is owing, no doubt, to their earliness, and deprived of the light they get when they first come up they might not succeed. The Dicentras are suited to such locations, especially *D. cucullaria* (Dutchman's Breeches), and the one commonly called Squirrel's Corn, *D. Canadensis*. An admirable little plant for shade, and one easily established, is Rhue Anemone, *Anemone thalictroides*. It closely resembles the Wind Flower, *Anemone nemorosa*, but lasts longer and is easier to establish. The European Wood, or Snowdrop Anemone, *A. sylvestris*, is another pretty species which likes shade and moisture. The Hepaticas, though they do not require as much shade as some other plants, like shade some of the time at least, and, unlike many of the early plants, they have abundant foliage that lasts until the following spring. They are benefited by a good supply of well-composted manure, and do best if they are not disturbed after they are once established. The Wild Gingers, or Asarums, are shade-loving plants. Though not showy, their foliage is good, and they are useful in many ways. All of our native Meadow Rhues do well in shade, and the early one, *Thalictrum dioicum*, is useful for shady locations, and not as tall as some other species. Both of the Actæs, or Baneberries, though not always found in shade, are well suited to

this condition. Their flowers are pretty in their season, and their fruit is quite as interesting. The Blue Cohosh, *Caulophyllum thalictroides*, and the smaller Solomon's Seal, *Polygonatum biflorum*, are good plants for shade, not so much for their flowers as for foliage. They form fine large clumps during a good portion of the summer. Both species of Twisted Stalk, *Streptopus roseus* and *S. amplexifolius*, do well in shade. I have found that they require more than one season to become established. One of our common wild flowers in northern New England, growing in rich, moist woods, is the large Bellwort, *Uvularia grandiflora*. It bears transplanting well and makes a good showing during most of the summer. False Miter Wort, *Tiarella cordifolia*, is a very desirable plant for moist, shady places, as well as for the rockery. It is one of those species that can be used in various ways and flourishes in shade or sunlight. It is attractive in the front border, and when it has finished flowering its rich dark green foliage lasts throughout the season.

The majority, perhaps, of native Orchids prefer shade. The two yellow Lady-slippers are probably the surest of these to succeed. The little white one from the west, *Cypripedium candidum*, does well in partial shade. About all of our native Ferns like shade, and can be used in such locations with proper preparation of the soil.

Nearly all of these shade-loving plants attain their greatest size in woodlands in a moist, rich, black soil. When they are transplanted into a shady place that has little fertility this want must be supplied, and this can best be done by adding rich soil from the woods. When planting in the shade of trees it is also necessary to supply moisture during dry weather, since trees rob the soil of both fertility and moisture.

F. H. H.

Meetings of Societies.

Nebraska State Horticultural Society.—I.

THE annual meeting of the Nebraska State Horticultural Society was held in the State University from January 15th to 17th inclusive. Last year the plan was adopted of confining the meeting chiefly to the apple, so that the report when issued should be in the nature of a monograph on the subject. The same plan was continued this year, except that three fruits were taken up for consideration—the grape, plum and cherry.

THE BOTANY OF THE GRAPE.

Dr. Charles E. Bessey read a paper on this subject, in which he said that there are about thirty-five or forty species of the Grape in the world, of which North America has from eighteen to twenty-three, according to the number regarded as true species. Europe has one, which also extends into northern Africa. Tropical or Central America has two, the East Indies two, and the remainder are found in eastern Asia. It will thus be seen that North America has more species than all other parts of the world together. The genus is confined mainly to the north temperate regions. Few species reach into the tropics, and none at all are found in the southern hemisphere.

For horticultural purposes only eleven species need be considered: (1) These are the northern Fox Grape, *Vitis labrusca*, represented in cultivation by Concord and Catawba; (2) The Mustang Grape, *V. candicans*, represented by Elvican; (3) The Summer Grape, *V. æstivalis* (Herbemont and Eumelan); (4) The Downy Grape, *V. cinerea*; (5) The California Grape, *V. Californica*; (6) The Sand Grape, *V. rupestris* (Munson and America, hybrids with *V. æstivalis*); (7) The Riverside Grape, *V. vulpina* (Clinton, Elvira and Tayler); (8) The Red Grape, *V. palmata*; (9) The Frost Grape, *V. cordifolia*; (10) The European Grape, *V. vinifera* (Black Hamburg and White Chasselas); (11) The southern Fox Grape, *V. rotundifolia* (Scuppernong and Thomas).

The northern Fox Grape has given us nearly all of our best varieties, but this is, no doubt, chiefly due to the fact that this was the species which our forefathers found when they began to improve the native grapes. Yet its distribution, entirely east of the Alleghany Mountains, indicates that it is really less adapted to the needs of the greater portion of the country than some of the other species.

The form of the Sand Grape has been modified till it is almost a bush, and not a climbing plant, like the others. It sometimes has no tendrils to climb with, even if it were not in a region in which there are few trees and shrubs to cling to. The Munson Grape, a cross between this species and the Summer Grape, has been reported to stand a temperature of

twenty-seven degrees below zero. This is a particularly interesting fact, since both of the parents are found in southern latitudes, and this seems to show that it does not always follow that the offspring will be tender if the parents are tender.

The Riverside Grape is the common species in Nebraska. Owing to its wide distribution, this is a desirable parent to use in aiming to secure hardy varieties. Professor Munson says that this must enter into all varieties which are expected to endure the extreme winters of the north-west.

The Red Grape occupies a small region near St. Louis. This is a recent variation from the Riverside Grape, with bright red canes when young and deeply lobed leaves. It is quite ornamental, and has proved hardy at the Arnold Arboretum.

The European Grape in a wild state is very similar to our Frost Grape, with small blue berries. The wonderful improvement which has been wrought in this species leads us to think that we can do almost anything with our best native Grapes by patient and well-directed effort. The European Grape is not important in Nebraska at present, but it will undoubtedly yet be grown here, since it is not the climate that prevents its growth, but the phylloxera, and this can be overcome as well here as in other countries by grafting on the proper roots. The great variation in color which has occurred in varieties of *Vitis labrusca* is an encouraging feature in the possibilities of future improvement from this and other species.

THE PROPAGATION OF THE GRAPE.

This was the subject of a paper read by G. A. Marshall, of Arlington. For commercial purposes propagation from three-eye cuttings is the most practicable way under ordinary conditions. These are taken in the fall, buried in the ground, tops downward, and covered with three or four inches of earth. In Nebraska this needs to be wet thoroughly and then covered with two inches more of soil. When freezing begins the whole is covered with about six inches of hay or similar material. In spring the covering is removed, with the exception of about two inches of soil, and the bed is surrounded with a board frame for protection from winds. This two inches of soil which covers the cuttings must be kept wet without fail. No rotting need be apprehended, and they should be kept as warm as possible, with the frame covered in very cold weather. The time to plant is when they begin to send out roots, which will usually be within fifteen or twenty days after the upper part of the covering is removed. The cuttings should lean toward the north or east when planted, and the soil should be firmly packed about them, and the row covered with a ridge of soil till the roots are thoroughly started.

BREVITIES.

Some of Rogers's hybrids give good satisfaction in the south-eastern portion of the state. For general market purposes Moore's Early proves profitable, owing to its season, though it does not yield more than half or two-thirds as much as Worden or Concord. It bears heavy manuring. The Worden is the best all-round market variety, because it ripens here before competition becomes so close from other localities. Among newer varieties, Eaton is giving satisfaction wherever tried. It ripens with Worden, appears to be as hardy as Concord, and is one of the largest and handsomest black grapes grown.

Grafting the vine above ground was recommended so that the cion cannot send out roots of its own, for this will partially overcome the value of a stock which resists phylloxera. Even varieties of *Vitis labrusca* are somewhat subject to the attacks of this pest, and this susceptibility appears to increase with the age of the vine. The Delaware seems to be affected worse than any other variety.

Professor N. E. Hanson stated that in an experimental hybridizing at the Iowa Agricultural College varieties of Grapes and Strawberries from Manitoba were used, with the hope of securing increased hardness in the offspring. The hardier plant is used as the mother in all cases. He finds the secret in keeping pollen to be in getting it thoroughly dry before it is corked up in the vial.

Western New York Horticultural Society.—I.

MORE than five hundred members of this progressive society met in Rochester last week at its fortieth annual meeting. Nearly all these men are actively engaged in some business connected with fruit-growing, and, perhaps, these meetings bring together more men who are skilled in the cultivation of orchards and vineyards than can be found anywhere else in the country on any occa-

casion. At this meeting, like its predecessors, papers were read by many men of science, from this and from other states, and the business, as usual, was conducted with admirable promptness and efficiency. The officers elected for next year are William C. Barry, of Rochester, President; S. D. Willard, of Geneva, First Vice-president; Secretary and Treasurer, John Hall. We present this week in a condensed form some of the addresses and discussions:

PRESIDENT BARRY'S ADDRESS.

UNPRODUCTIVE APPLE ORCHARDS.—During the past summer I have had occasion to visit several localities in western New York, and I have been greatly impressed with the number of old, worn-out apple orchards, which are an eyesore wherever found, and which should be cut down and used for firewood. It is difficult to understand why so many dead and dying trees have been allowed to stand after having outlived their usefulness. The beauty of any farm is marred and its value depreciated by these old trees. I ask the members of this society to give aid in remedying this condition of things. The public good and local pride demand this. Again, the number of orchards of medium age which are partially or totally neglected is very large. These orchards should be taken care of or destroyed. Few of us realize how much valuable land is unproductive owing to its condition. In most cases, by plowing the sod and fertilizing and pruning, vigor, health and fruitfulness can be restored. Many hesitate to undertake the work on account of the expense involved, but it is evident that there has been too much delay already; we are really forced to meet an emergency and to do something at once. As to the advisability of cultivating and pruning there is no question. A thorough cleaning up will completely change the aspect of our fruit farms and homes, and many places can be made valuable which otherwise are worthless. A grower at Carlton, Orleans County, stated recently at a farm institute that he had thinned out his orchard to the extent of 600 trees, and sprayed the remaining 600 three times with Bordeaux mixture. As a result he marketed 2,400 barrels of fine apples at an average price of \$2.13 per barrel.

FRUIT AS FOOD.—The use of fruit as an article of food is becoming more and more general, though the amount consumed in families is very small compared with what it should be. Very many labor under the false impression that fruit should only be taken at the end of the meal. Fresh fruit should be partaken of at breakfast for at least six or nine months of the year. In the morning it is cooling, refreshing and easily digested. Perfectly sound, ripe fruit should be secured in the autumn for the winter's supply. In this region it is easy to secure apples and pears of the best grades. Wealthy Europeans send their orders annually for a year's supply of fruit to this country, and have it shipped directly to their homes, paying a good price for a superior and selected article. The day is not far distant when it will be possible for all who care to indulge in it to have fresh fruit on their tables the year round, and in this locality it need not be a luxury, for the prevailing prices will be so low as to enable all to buy, and more fruit with less meat will certainly conduce to a healthier condition of body and mind.

COMMERCIAL FRUIT GROWING.—Early in the year the prospects for a large apple crop in this vicinity were bright, the trees blossomed full, but when the fruit had attained the size of hickory-nuts it dropped; this was probably due to a heavy frost in May; then it was predicted that there would be no apples; however, there has been a crop harvested much larger than was anticipated. Many orchards have paid well. Much fruit is at present in cold storage in the expectation that prices will advance later on. I see it stated that Mr. Wellhouse, of Kansas, has marketed 23,000 barrels from sixty-five acres, and that he has produced fourteen crops in fifteen years. We can hardly expect results equal to this, but still the outlook is not discouraging when we consider how neglectful we have been in many respects. In plain English, many of our orchards have been starved. If the proper nutrient be supplied, a change will take place. Surface cultivation and application of potash will do more than anything else to make the orchards remunerative. The time has come when it will not pay to send poor fruit to market in the hope of getting good returns. The large quantities of fruit from California, sent annually to the eastern markets, have made competition keen, and it will become necessary to do as the Californians do—pack selected fruit in small attractive packages. The fertility of our soils has been exhausted, a fact we have to look squarely in the face. Where fruit growing is unsatisfactory it is mainly due to this cause;

with fertility restored and good cultivation, the prospects are favorable for profitable crops.

EXHIBIT AT THE STATE FAIR.—The exhibit made by this society at the State Fair, held in Syracuse, was remarkable, not alone for its extent and completeness, but for the superior quality of the fruit and the attractive manner in which it was displayed. Taken as a whole, it is certain that such a display could not be duplicated anywhere in the United States or Canada. Great care had been bestowed on the nomenclature, so that few, if any, errors could be detected. The exhibit was intended to show, and the object was well accomplished, the capabilities of the genial climate and fertile soil of western New York. Few who enjoy the privilege of living in this region realize the advantages over those who live where fruit is scarce and hard to obtain. The favored few have no monopoly of these delicacies here; every one can enjoy them as freely and as abundantly almost as the air we breathe, and these exhibitions are made with a view of showing what every landowner should and can have if he be so disposed.

SCHOOL YARDS.—I have on a former occasion suggested to this society the importance of adopting measures by which the grounds around our schoolhouses may be relieved of their forbidding aspect. A little labor and expense will transform the surroundings into delightful pleasure-grounds. The trees, shrubs and plants for the purpose can be obtained in any of the near-by woods. The improvement of school-grounds will accomplish a double object—the taste of the pupils will be cultivated, they will become familiar with many charming objects which would otherwise be overlooked, and the garden will serve as an example and pattern for the neighborhood. In the selection of teachers I believe preference should be given to such as are known to be lovers of Nature and who will take pains to awaken an interest in a study of plants. I believe that opportunities for great improvement lie in this direction, and this can be brought about with little expenditure of money.

THE SCIENCE OF TILLAGE.

Professor I. P. Roberts read a paper which explained how cultivation in many different ways made orchards and vineyards productive and profitable. Part of this excellent paper is herewith given:

Most arable soils contain large amounts of dormant plant-food; all soils contain a small amount of plant-food which is available; some plants have the power of setting free this nourishment to a greater degree than others, our common Mullein furnishing a notable example of this power. It is evident, then, that either plants which have unusual power to secure nourishment must be grown on lands which fail to respond, or more nourishment must be provided if the higher and more exacting plants are raised. There is enough of nearly all the elements of plant-food, including potash and phosphoric acid, in the first sixteen inches of ordinary soils to supply crops for several generations if the plants could only get hold of it. There is a great deal of nitrogen, too; more of it in the subsoil than in the upper layers, and this is part of the reason why Clover, Peas, Beans and other deep-rooted plants are so valuable.

When plants languish, if adapted to the climate, it is evident that the soil has not been properly prepared, so that the plant-food in it is not available, or that there is not sufficient moisture to transfer it from the soil to the plant. Cultivation may be made to obviate partly or wholly all these difficulties. Plant-food which is unavailable is useless, and one of the chief objects in cultivating the soil is to prepare this for use by setting it free and diluting it with water so that it can be taken up by the roots of plants, or by opening and loosening a soil that is too wet or too compact to allow the plant-food to be liberated by fermentation.

If water carries plant-food downward it can also be made to carry it upward from the subsoil to the feeding roots of the plant. The soil-water, which in the day-time rises, not only brings with it plant-food, but it enables the plant to secure the nourishment already in the soil around its roots.

Cultivation is a powerful factor in setting free plant-food. It increases the solubility of plant-food by crumbling, rearranges the particles of soil, breaks them up so that no two of them are in the same position that they were before the tillage, and the particles present more surfaces for the roots to act upon with their living chemistry. Cultivation when properly done also hastens nitrification and thus helps to prepare for use the important and expensive element of nitrogen so essential to plant-growth.

Cultivation greatly assists the soil in retaining its moisture in dry weather. The great orchards and vineyards of Califor-

nia are cultivated deeply many times during the early part of the season, and although no rain falls from April to November, the trees and vines prosper quite as well as where there is an abundant rainfall. During the winter months in most of the California fruit valleys the soil is filled with water by frequent rains. By plowing the vineyards and orchards in April, when they have become dry enough to do so, and by keeping the harrows, cultivators and gang-plows at work during May and June, and sometimes into July, nearly all of the moisture of the subsoil is conserved and made available for the growth of the plants. One great object in cultivating the land is to form a mulch. While in early spring, cultivation, as has been said, may serve to dry the land out and open it to absorb heat; later in the season, just the reverse of these conditions is desirable. When a layer of a few inches of dry porous earth is spread like a blanket over damp ground the moisture will not only be kept from evaporating, but plant-food will be set free and chemical action hastened. The mulch of earth made by light tillage will shade the land and keep it cool in hot weather, and in every way be beneficial. In California four or five tons of water, which would otherwise evaporate from every acre, are held for use in the soil by this mulch of surface tillage.

Before the orchard or vineyard is set, the ground should be plowed, subsoiled and summer-fallowed for an entire season, because there is a vast amount of plant-food in the soil, and it is cheaper to secure it by cultivation than to add plant-food from outside sources. Then, too, the thorough preparation of the soil brings it into firm physical condition, serves to aerate it and also to promote drainage. Too much stress cannot be laid upon the thorough preparation of the land for orchards and vineyards, or any other crop that is to remain upon the land for several years. After the plants have been set the surface cultivation should go on as carefully and systematically as though a crop were expected immediately.

On most fruit-plants a light dressing of phosphoric acid (in some form of bone, say), when the trees and vines have come into bearing, will produce most satisfactory results, and in almost all cases where plant-food is slightly deficient a dressing of potash will be found to be extremely beneficial. A sowing of ten or fifteen pounds of Crimson Clover to the acre at the last cultivation of the orchard will furnish, unless in exceptional cases, all the nitrogen needed when it is turned under next year. By a little observation the planter should learn to know by the size and character of the leaf, by the growth of bark and the amount of wood made each season, the character of the plant-food which should be added.

Mr. James A. Root spoke of the good cultivation practised by the Mennonites in Kansas and Nebraska, on account of which they had crops last year while their neighbors had none. By thorough cultivation in a dry time we can often get a better crop than the average in a wet season.

Recent Publications.

The forty-fourth and forty-fifth parts of the English edition of *Lindenia*, or an Iconography of Orchids, published by Lucien Linden, of Brussels, has just reached us and maintains in the beauty of its illustrations and the excellence of the descriptive matter which accompanies them the standard set by this important work in its earlier numbers. In the present parts there are figured *Cypripedium Denisianum*, a hybrid between *C. seligerum* and *C. superbiens*, and described as a strong grower, very prolific, and one of the most desirable hybrids of its class; *Cattleya Mossiae*, var. *Treyeranæ*, a variety with broad rose-colored petals and sepals and a lip covered by a bright golden-yellow blotch on which the close red streaks appear as dark purple passing into maroon; *Odontoglossum Pescatorei*, Prince of Orange, a variety of distinctive character, due to the orange-yellow-ground color of the segments and the shape of the lip; *Cattleya Cupidion*; *C. guttata*, var. *tigrina*, a distinct form of one of the best-known and longest cultivated species of the genus; *Catasetum macrocarpum*, var. *Lindeni*; *Cypripedium Charlesworthii*; and *Mormodes Cogniauxii*, a recent introduction from Columbia, that flowered for the first time in Europe last June, in the garden of the Société de l'Horticulture Internationale of Brussels, and was dedicated to Monsieur Alfred Cogniaux, who has described the Brazilian Orchids in Martius's *Flora Brasiliensis*.

Notes.

Experiments conducted at the Alabama Experiment Station with Ragi Millet, Eleusine coracana, and Kodo Millet, a species of Paspalum, both obtained from the Madras Presidency, seem to prove that these plants will make good pasture crops for cows and other stock, and also be profitable hay-producing plants in the southern states.

A Tennessee paper states that Mr. Thomas L. Walker, seventy-five years ago, planted four walnuts on his father's farm, near Knoxville. Mr. Walker died ten years ago, when the four Walnut-trees grown from the seed he planted averaged four feet in diameter, and their value, if cut and sawed, would have been not less than \$400 a piece.

The *Pacific Rural Press* gives an illustration of the Calla Snowflake, which is one of Mr. Burbank's new creations. It is a seedling of the dwarf variety Little Gem, but its flowers never grow half as large as those of that variety, and the leaves are also much smaller. The flowers are snowy white and gracefully moulded, and it is altogether the smallest Calla yet produced.

We have received the first number of the *New Jersey Forester*, which is a bimonthly pamphlet devoted to the development of the forests of that state. It contains twelve pages of instructive matter, and the leading article, by Mr. Fernow, gives the best kind of advice to the owners of New Jersey woodlands. The pamphlet is the official organ of the South Jersey Woodmen's Association, which was organized to protect the forests in that section, to insist upon the enforcement of laws in relation to forest-fires, and to encourage such management of woodlands and waste lands as will help to conserve the water-supply, protect game and insure a continued supply of forest products.

The *Southern Lumberman* says that mahogany logs from the east coast of Africa have got as far west as Louisville, Kentucky, and adds that it is much cheaper than the mahogany from Central America and Cuba. From these Mahogany forests in Africa it is said that twelve million feet of lumber have already been cut and exported, and they promise to yield an immense revenue to the British and French colonists who have seized upon the territory. The wood has a tinge of pink in contrast with the somewhat reddish color of the American variety, and some of the squared logs which have been imported are two by three and a half feet in size. We may add that this African mahogany is the wood of Khaya Senegalensis, a tree which belongs to the same family as the true Mahogany, and is closely related to it. It is not so desirable a cabinet-wood as the Mexican or Cuban Mahogany, but is more like the Central American wood. Occasionally there are logs richly figured, and these have been manufactured here into very attractive veneering.

At the late meeting of the Ohio Horticultural Society, Professor Green, of the State Experiment Station, in a report on new fruits, stated that Eldorado promises to take a place among standard varieties of Blackberries. It has endured a temperature of twelve degrees below zero, and is certainly hardier than Lawton or Erie, which it nearly equals in size of berry, and probably is as hardy as Snyder or Ancient Briton. Of larger-fruited berries, Minnewaska is about the hardiest. Among Raspberries, the variety Ebony bears black berries, which present a beautiful appearance in a basket. It is of medium size and season. Eureka commences to ripen early, and bears very late, covering the entire season of Palmer and Gregg, and yielding about as much as both together. The Gault seems to be an exception to the so-called ever-bearing varieties, which are generally worthless, in that it is vigorous and exceedingly productive. The main crop begins to ripen with the Gregg. The berries are large and firm, and the plant bears through a very long season.

A correspondent of the *Strawberry Culturist* writes that he last year tried the so-called trench system which he heard was practiced at the Bryant Nurseries, in Quincy, Illinois. The plan is to dig trenches sixteen to twenty inches deep, leaving a space of but six to eight inches wide at the top between them. The trenches are then filled with straw and coarse manure, which is trodden and pounded firmly. The plants are set on the ridge between the trenches, and the litter is said to retain water enough from the early rains to carry the crop through the dry summer. The claim is that larger and more berries are produced, and by cutting the runners along the edge of the straw the same rows may be kept for years,

with only a narrow strip to weed. Certain difficulties in the mechanical construction of such beds at once suggest themselves, and there seems to be no good reason why water will remain so much longer in straw than in earth. We should counsel novices to proceed slowly if they propose to make any experiments with the new method.

A correspondent of the *Gardeners' Magazine* writes of his success in raising plants of Pteris, Adiantum and other Ferns from spores in the following way: With a hammer and chisel he cut a basin three-quarters of an inch deep in the wide side of a brick, leaving a ridge around the edge. Into the bottom of this depression he placed a thin layer of finely pulverized brick-dust made from the particles which he had chiseled out of the cavity. On this layer he sowed the spores of the Ferns, and then covered the brick with a sheet of glass which rested on the edges of the basin. He then set the brick in a shallow dish or saucer in which water was constantly kept, and the whole was placed on the top of a pipe under a stage and properly shaded. The house had a flow and return pipe only, but, of course, all that is needed is some position where proper warmth and shading can be given. The porous brick will take up from the little water kept in the saucer enough to supply the needed moisture to the spores, and when the young Ferns are ready to prick out, the layer of dust makes their removal simple and easy. The writer thinks that amateurs sometimes fail in raising Ferns from spores by keeping the temperature low, when too much water sours the soil, or too little cakes it and kills the spores.

Raffia, which is the cuticle of the leaf of the Madagascar Palm, has been for some years dexterously plaited in ladies' hats, although most of the wearers have been innocent of the material which formed their head-dress. In the same way bast, or the inner bark of Hibiscus elatus, another fibrous substance which gardeners use for tying, has been pressed into the service of the milliners after being bleached and dyed, and when it is so treated, and twisted or braided, it forms a very light lace-like material. The bark of the Baobab, Adansonia digitata, after being well bleached, is also used for the same purpose, but many of the milliners' materials are so completely changed by the different processes which they undergo, that it is hard for an expert to determine their botanical origin. Split willow wood, which under the name of chip was largely used thirty or forty years ago for hats and bonnets, is once more bleached and dyed and plaited for this purpose, while single fibres of the Sisal Agave and Manilla Hemp, Musa textilis, are placed side by side and united by means of gelatine into a tape-like form and submitted to a heavy pressure, which not only gives a thin material like flattened straw, but one with a remarkable gloss, due to the pressure. The varieties of design in which these Sisal and Manilla plaits are used are endless, and there is a great demand for them all over the civilized world.

Besides potatoes, Bermuda is now sending limited quantities of onions, beets, lettuce, string beans, spinach, parsley, carrots, peppers, kohlrabi and strawberries, and small lots of beans, onions and okra come from Cuba. The importations of potatoes from Europe since the first of October have fallen short of those received last year by 150,000 bags, while the receipts of domestic potatoes during the same time in this city has been increased by about the same amount. The first rhubarb of the season in this market is from Long Island hot-houses, and sells at retail for twelve and a half cents a bunch. Catawba grapes are occasionally seen in fair condition, a small basket costing twenty-five cents. Selected Spitzenberg apples are quoted as high as \$6.00 a barrel at wholesale, Greening, Northern Spy and Baldwin apples ranging from \$3.00 to \$4.50. A few Bellflower apples find ready sale in the fruit-stores at thirty cents a dozen, showing that they are considered choice fruit here, although in Philadelphia markets they are esteemed more highly. Some of the showiest and best Newtown pippins seen here this winter are now coming from Vermont. These bring from sixty cents to \$1.00 a dozen, or \$8.00 a barrel. The last Beurre d'Anjou pears, from Rochester, are now in the market, along with large and showy Easter Beurre pears, from California, which have been carried along in cold storage. The latter cost \$1.00 a dozen. Winter Nelis, Comice and P. Barry are in fair supply, and bring from forty to seventy-five cents a dozen. There is nothing to add to what has already been said about the destruction of the orange crop in Florida. The scarcity of all citrus fruits will probably have a tendency to hurry forward the supply from California, and a few small sample lots have been reported already.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST-OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, FEBRUARY 6, 1895.

The Forests on the National Domain.

WHAT is to be the fate of forests on the national domain, and how is the much larger forest area of the country, now in private hands, to be managed in the future, are questions which, a few years ago, would have excited but trifling interest anywhere in the United States. The current issue of *The Century* magazine shows that these matters are now subjects of serious study by many thoughtful Americans. The editor of a great periodical is a good judge of what subjects are of immediate popular interest, and the fact that *The Century* not only makes a distinct proposition of its own for action in the matter of forest-preservation, but devotes ten pages to setting forth the views of persons who, from their official standing or personal knowledge, are qualified to say something worth hearing on the subject, is an evidence that we are gradually nearing the time when indifference and lethargy in relation to this matter will give place to an active realization of the fact that the prosperity of our country is directly connected with the proper management of our forests.

Six years ago, when speaking of the nation's forests, it was urged in this journal that all forest-lands belonging to the Government should be withheld from sale until an examination of these lands, and of the agricultural lands depending upon them for water-supply, would show what tracts of timber could be put upon the market without threatening important interests in the country below them. For the protection of these forests against injury from man and beast, it was advised that, pending this investigation, the guardianship of the forests on the national domain should be entrusted to the United States Army, and that this examination of the national forests should be conducted by a commission, appointed by the President, of men able to report upon the magnitude and quality of our forests, and upon their relations to other interests. No commission was appointed, however; perhaps the time was not ripe for such a plan, modest and moderate as it was; but certainly if such a commission had then been named, we should now know more about our forests than we do. In *The Century* symposium a man so well qualified to speak as Mr. Bowers, the Assistant Commissioner

of Public Lands, declares that estimates of the amount of forest-land owned by the Government vary between the lowest and the highest by twenty millions of acres, which means that we have no absolute knowledge whatever. And since no one can do more than make a rough guess at the area of these lands, any surmise as to the amount of timber growing on any portion of them, or of its value, or of the ease or difficulty with which these woodlands can be made permanently productive, would be wilder still. It seems, then, that the need of a board of investigation is quite as urgent to-day as it was when the proposition was first made, and *The Century* now advocates the creation of a commission, composed of men whose reputation will give their recommendations weight, and whose duties shall be to study the whole question of forest-preservation, and report fully upon it to Congress.

Such action need not interfere with any other legislation, for the first thing to be done under any scheme would be to get more knowledge, and no better way of obtaining information about our forests can be devised than that of sending competent men to the ground to examine them. *The Century* also revives the other recommendation that until this report is made all forest-lands should be withheld from sale. And why not? No private interest can suffer by such a delay. No one has an inalienable right to demand that the Government shall sell him a wood-lot. It is true that there are delicate questions involved in the necessities of pioneers, who need wood for fuel or timber for mines. This is one of the very points which such a commission should be called upon to study, and certainly it would not be unwise for the Government to hold fast to all its lands until they could be disposed of more intelligently.

There seems to be little question as to the advisability of employing the army as a police force while this investigation goes on. Captain Anderson, who has been in command of the troops in the Yellowstone National Park, ought to be a competent judge in this matter, and in his contribution to the symposium it is stated that the soldiers of his command have served every purpose of a forest-guard most satisfactorily. There have been suggestions about lectures on forestry in West Point, with an experimental forest-reservation on the Highlands, but upon these points there are differences of opinion. It is admitted that there would be an advantage in giving officers of the army a brief course of forest-study, and there are objections to the plan which it is not necessary to state, but there seems to be no question that the army is the one body now properly organized to take charge of our forest-reservations, to protect them from fire and trespassers and to execute any regulations imposed upon them by Congress. Such police work does not need any exhaustive knowledge of forestry, and undoubtedly the army as it is can protect the reservations and all the national forests as thoroughly as they have protected Yellowstone Park. Of course, this service would only be temporary, for the time is coming when a policy, which only means mere protection of the woods from timber thieves and browsing animals and fire, must be replaced by an active system of reproductive management such as is used in other industries of this country and in the forests of other civilized nations.

It is to be hoped that the press of the country will unite with *The Century* in this recommendation to Congress. No one doubts that something ought to be done, and done now. No one has suggested anything that will cause less disturbance, and which, with so small an outlay, promises so much. No elaborate machinery is called for, no large appropriation. Congress is simply asked to help secure the knowledge which is needed before an intelligent and consistent scheme can be devised for managing this great property which is now wasting so rapidly away before our eyes. Of course, we must ultimately have some comprehensive system of forest-management. No such system can be carried into execution, however, unless it is based

upon consenting and upholding public opinion, and we can imagine no better means of creating this prevailing sentiment than the publication of such a report as is contemplated. It will be a long time before the country will be prepared for any system of forestry which will need the supervision in all its details of persons skilled in the refinements of the highest scientific practice. But we must begin right. Mr. Fernow very properly insists that our first need is common-sense treatment of our natural woods. But common-sense treatment is what our woods have never had, and they never will have such treatment until the people are instructed in the elementary principles of sound forestry. The inauguration of a common-sense policy will only come from the teaching and example of those who are masters of the whole subject, and who foresee that the great advantage of such a policy is that it will be a broad-set foundation for more scientific and rational practice. We need the very best of counsel at the outset, and the more thoroughly the problem is studied now the more certainly shall we avoid fundamental mistakes which it would be the work of years to correct.

Fructification of the Cork Oak.

IN Professor Coutinho's valuable paper on the Oaks of Portugal* there are some interesting statements regarding the fructification of the Cork Oak, *Quercus Suber*, which has been generally considered as an annual fruiting species, but which in certain localities in Portugal is found to produce both annual and biennial fruit. It would be interesting to learn whether any of the native species on our southern seaboard ever behave in a like manner. The only analogous case, so far as I am aware, is that of *Q. myrtifolia*, a normally biennial fruiting species, which Dr. Mellichamp finds producing annual fruit plentifully at Bluffton, South Carolina. With the object of drawing the attention of our students of Oaks to this subject I translate the following extracts from Professor Coutinho's paper:

The flowering of the Cork-tree is with us subcontinuous. It is most abundant from April to July, but occurs in almost all the other months, and appears to be interrupted only by the extreme heat of summer or cold of winter. Maturation takes place from August to February, the fruit ordinarily falling in three more or less distinct crops—the first, which our farmers call "bastão," in September and October; the second, called "lande," in November, and the third, which constitutes the "landisco," or "lande serodia," in December and January. It should be remarked that most of the time these fruits are inserted in shoots bearing leaves of the year, and are evidently produced and developed in a single season, but in some cases the fruits produced from the last flowers of autumn or winter, not meeting then the warmth necessary for maturing, pass the winter in an undeveloped condition, and only ripen in the following spring or summer after the growth of new shoots, appearing then mature on the woody branchlet of the previous year, which may be at that time furnished with or bare of leaves. This fact appears due more to particular weather conditions than to an especial organization of the trees in which it occurs; in short, it is not constant with a given individual, nor is it exclusive, the same individual being able to produce fruits plainly annual.

* * * * *

Many botanists consider the Cork Oaks of Europe as belonging to two species, one chiefly characterized by annual fructification and the persistence of the leaves for two or three years (*Quercus Suber*, L.), the other by biennial fructification and annual persistence of the leaves (*Q. occidentalis*, Gay).

Recent botanists and silviculturists have frequently discussed the existence of *Quercus occidentalis* in the Peninsula, and some have even doubted its being a good species. Brotero, in the *Flora Lusitanica*, includes all the Portuguese Cork Oaks in the Linnaean species, *Q. Suber*, and makes no remark about the maturation of the fruit and persistence of the leaves of these trees. Later, Dr. Welwitsch considered the Cork-trees of Cintra as belonging to *Q. occidentalis*, and the specimens sent to France, and studied by Gay himself, were determined by him as belonging to his new species, and as such cited in De Candolle's *Prodromus*. Lastly, Sr. Barros-Gomes dis-

puted this assertion, affirming that the Cork Oaks of Cintra belong to the Linnaean species, and denying that *Q. occidentalis* should be considered a good species. We transcribe the principal reasons he adduced:

"The Cork-tree of Cintra collected by Welwitsch, and determined as *Quercus occidentalis* by the followers of the new classification, does not have fruit more biennial in appearance than many others, in which there is no doubt of its being in fact annual, and only apparently biennial. It is very common in Portugal to find an apparent biennial maturation of fruit that is really annual, because the growth of the Cork-tree with us often admits the formation of one, two, or even three new growths in a single year, exactly as occurs in the common Oak, *Q. pedunculata*.

"The prolonged flowering of the Cork-tree, commencing in April, hardly ceases during the dry season, and is renewed with the first rains of autumn, giving rise to two or three successive crops of acorns, the last of which matures in January. It is often accompanied with successive new growths and partial falling of the leaves of the year, so that the lower branches, only a few months old, become bare, and have the biennial appearance to which we refer. In the common Oak, whose foliage is wholly annual, fruit is found apparently biennial by insertion, and, nevertheless, plainly annual by the coexistence of leaves with the same insertion.

"The foliage of the Portuguese Cork-tree, with annual fruit, is not persistent, as a rule, during two or three years, as Mathieu affirms of the species he describes as *Quercus Suber*, nor by any means is it always annual as in the one he calls *Q. occidentalis*, but it varies with the meteorological behavior of each year or with local conditions, in some years wholly falling, in others persisting more than one and sometimes two years.

"It does not appear that our Cork-trees, even those of Cintra, have from January to April acorns in immature condition." (*Condic. Flores de Port.*, pp. 56, 57.)

Contrary to the last statement of Sr. Barros-Gomes, we found in 1886, toward the end of February, living fruit but little developed on specimens gathered near S. Thiago de Cacem, fruit evidently produced the previous season, and which could only mature in the season to come. With this fact was correlated a very peculiar form of the scales of the cup exactly agreeing with the Cork-trees of Cintra, identified as *Quercus occidentalis* by Welwitsch and by Gay himself. Furthermore, the existence of some bundles in the central parenchyma bounded by the arc of the fibro-vascular bundles of the petiole, was observed, like those which occur in the trees of Cintra, and which, according to De Candolle, is peculiar to *Q. occidentalis*, not being found in *Q. Suber*. These reasons led us to affirm the existence of *Q. occidentalis* in Portugal in our *Esboço de uma Flora Lenhosa*, lately published.

To-day, however, after a careful study of very numerous specimens, living and dried, from many parts of the country, we are obliged to greatly modify our former opinion and have arrived at the following conclusions:

1. The Cork Oak in our climate has an almost continuous flowering, as Sr. Barros-Gomes well says. We have seen specimens in flower (living or dried) in the months of January, February, April, May, June, July, September, October, November and December.

2. With this almost uninterrupted flowering there is a corresponding fructification similarly uninterrupted from the end of August till February. It is to be noted—a fact not found in our other Portuguese Oaks—that it is common to find on the same branch fruit in very different degrees of development; for example, a mature fruit in the axil of one leaf, and very small fruit, hardly formed, in the axil of a higher leaf.

3. The last fruits formed before the cold weather may persist through the winter and develop the following spring or summer. We have seen specimens in this state (with very small living fruit, from December to March) from S. Thiago de Cacem (above referred to), from Cintra, from Coimbra, from Portello and from Alemtejo. These fruits are produced in one season and grow and ripen during the following one, contrary to the statement of Sr. Barros-Gomes.

4. It is certain that the Cork-tree frequently makes two growths in one year, but we consider it quite easy in this case to distinguish the false biennial insertion of the fruit. When the tree makes two growths in a single year, the second or summer shoot is more pubescent, less woody, with narrower leaves, and has thus a characteristic appearance.

5. These biennial fruits are not constant in certain trees, but appear or not according to localities or seasons, and on the same trees annual fruits may be developed also. In proof of this assertion we will say that in the end of last February,

while examining carefully the Cork-trees of Cintra, which usually fruit abundantly, we found very few biennial fruits, and on the same branches we saw the cups of fallen acorns with annual insertion. We will add that in Welwitsch's specimens, collected at Cintra, many are found with mature annual fruit, to one of which he affixed the following note: "Probabiliter nil nisi forma Q. Suberis, L., squamis cupularum plus minus hebetatis. Fructus pleniter maturi et alii sat juveniles, nec non fructus maturescentes saepius in uno eodemque pedunculo inveniuntur!!" We will add, moreover, that we examined from Coimbra, whence we had numerous biennial specimens, some others perfectly identical, with annual fruit, and Sr. Moller, at our request, examining again (the end of February) these trees, found very few biennial fruits, this apparently not being a common occurrence there.

6. It is no wonder that in certain places of great humidity, as Cintra, Coimbra, etc., the Cork Oak has an almost continuous growth and easily produces biennial fruit. It is also in such places that other species of the genus *Quercus* (*Q. Lusitanica*, *Q. humilis*, *Q. pedunculata*) frequently make (especially the first) two new growths, an indication of more continuous vegetation.

7. It is worthy of note that in various parts of the country it is said that certain men experienced in rural affairs know in winter whether the following year will be abundant in "bastão" (the first crop of acorns) by the presence of very small fruit, which, in this condition, they alone recognize. This fact appears to confirm the accidental presence or absence of fruit in the process of biennial maturation.

8. From what we have said, the maturation of the Portuguese Cork-tree cannot be said to be strictly either annual or biennial, but rather sub-continuous, hardly interrupted by the cold of winter; and for this reason it is impossible to base specific distinctions on the differences of this maturation.

In the same paper there is an interesting account of the hybrid Oaks thus far detected in Portugal. Among the eight indigenous species, four of these supposed hybrids have been found.

Arnold Arboretum.

The White Elm in the West.

THE Elm is one of several trees that are invariably recommended for planting in the west, but for which hardly any economic use is known. The timber is tough and hard, and is used in making wheels and saddle-trees, but its use about the farm is limited, as it is not durable in contact with the soil, and it is very difficult to season. Too much can hardly be said of its beauty of form, but in close forest-growth this is of small importance. It is native as far west as central Kansas, and a little farther in Nebraska. It endures low temperature well, and large specimens are found along the Red River in North Dakota. Although its habitat is always near streams or lakes, where its roots have a constant water-supply, it makes better growth in dry situations than many other species, and is altogether superior for high land to Black Walnut and Cottonwood. Thus far it has been quite free from insect pests in the west, but it can hardly hope to escape the destructive beetle that is defoliating the Elms throughout the east. In South Dakota cut-worms often cause great damage to seedlings, and they even climb into two and three year old trees and eat off their leaves. The larva of the emperor moth also attacks the foliage.

In rapidity of growth the Elm is one of our most satisfactory hard woods. In the South Dakota Agricultural College plantations, at Brookings, White Elm planted with Box Elder six years ago now equals the Box Elder in height, though for the first three years the latter tree grew the more rapidly. In a plat of hard woods, White Birch grew most rapidly, then White Elm, Black Wild Cherry and Green Ash, with but little difference between the three first named. At Hutchinson, Kansas, in the railroad plantation, now about twenty-four years old, White Elm and Cottonwood were planted in alternate rows. The Cottonwoods now stand from fifty to sixty feet high, and the Elms are completely overtopped, being scarcely thirty feet high, and making feeble growth.

In another part of the plantation, where their neighbors are Honey Locusts and Silver Maples, they are doing very

much better. The Elm is a light-demanding tree, and does not succeed where overtapped by other species. At Farlington, Kansas, an Elm that has evidently sprung from seed in a plantation of Catalpa speciosa has outstripped the Catalpa both in height and diameter. No Elms were included in this plantation, and comparisons cannot be given. The trees at Brookings stand in a rich loam above stiff clay, and those at Hutchinson are in the sandy loam of the Arkansas valley, with water within ten to twelve feet of the surface—an ideal soil for the Elm.

Several of the newer streets in Denver, Colorado, are planted with White Elm, and under irrigation the trees fully equal the best growth observed in the east.

Foreign Correspondence.

London Letter.

DENDROBIUM WATTII.—This plant first flowered at Kew in October, 1882, soon after it had been received from Dr. Watt, the Indian botanist, who found it in Munipore. It was figured and described by Sir Joseph Hooker in the *Botanical Magazine*, t. 6715, under the name of *Dendrobium cariniferum*, var. *Wattii*. In 1888 Professor Reichenbach elevated it to the rank of a species because of its differing from *D. cariniferum* in having slenderer stems, narrower leaves, larger flowers and a terete, not triquetrous, ovary. Sir Trevor Lawrence exhibited it in flower this week, and it was awarded a botanical certificate, although it merited the highest award. The flowers are borne in pairs on short racemes, and there are six or eight flowers on the apex of each stem; these are two inches across, pure glistening white, with streaks and a blotch of deep yellow on the front of the labellum. In effect the flowers are equal to those of *D. infundibulum* (*Janesianum*), and nearly as fine as *D. formosum*, to which *D. Wattii* is closely allied.

SACCOLABIUM MOOREANUM.—This is a pretty little Orchid which we owe to Messrs. F. Sander & Co., who introduced it from New Guinea along with *Dendrobium Phalaenopsis*, and with whom it flowered in October, 1892. It is named in compliment to Mr. F. Moore, the keeper of the Glasnevin Botanical Gardens, where there is an exceptionally rich collection of Orchids. Two plants of it are now in bloom at Kew—one, the type, having rose-purple flowers, the other, white flowers. The plant is less than six inches high, with distichous leaves, four to six inches long by an inch in width, the apex bilobed. The scape is horizontal, six inches long, bearing a conical raceme, two inches long, of crowded small flowers, which in the type are a pleasing shade of rose-purple, the segments tipped with bright green, while in the variety they are milk-white, with green tips. As a garden-plant this species takes rank with such Orchids as *Saccolabium ampullaceum*, *S. Hendersonianum*, *Phalaenopsis Parishii*, *Masdevallia triglochin* and similar diminutive, but charming as well as interesting things.

MORMODES ROLFEANUM is handsome enough to be classed with good garden Orchids. It was introduced four years ago from Peru by Monsieur Linden, and named by him in compliment to Mr. Rolfe, of Kew. There is a colored plate of it in *Lindenia*, 1891, t. 289, and there is a plant of it in flower at Kew now. It has a two-flowered scape six inches long, and the flowers are as large as those of *Mormodes luxatum*, but colored tawny yellow, shaded with green on the sepals and petals, while the twisted lip is colored apricot-red. All the *Mormodes*, with their cousins, the *Catasetums* and *Cyanoches*, are worthy of cultivation, but, as a rule, they do not like to be cultivated; at any rate, they are rarely seen in good condition after they have had about two years of artificial treatment. They do best when grown in baskets suspended near the glass in a hot moist house till they have finished their growth, when they should be placed in a drier, airy house and rested thoroughly till the growing season comes round again. Of course, they grow in summer and rest in winter—that is, when they behave properly.

PHALÆNOPSIS F. L. AMES.—I lately saw a flower-scape of this fine Orchid which measured eighteen inches in length and bore sixteen flowers and buds, which had been grown in the garden of Lord Rothschild, at Tring. Messrs. J. Veitch & Sons created this hybrid by crossing *Phalænopsis amabilis* with *P. intermedia*, and first flowered in 1888, when it was named "in compliment to the late Hon. F. L. Ames, of North Easton, Massachusetts, a liberal patron of horticulture and the possessor of one of the finest Orchid collections in cultivation." The flowers are as large as those of an ordinary variety of *P. amabilis*, measuring three inches in diameter, and they are white, except the lip, which is lined and shaded with salmon-red. This peculiar color, together with the form of the lip, are the only marked indications of the other parent, *P. intermedia*, itself a hybrid from *P. rosea* and *P. aphrodite*; or, to be precise, a plant raised from these two by Messrs. Veitch, and flowered in 1886, proved to be the same as the *P. intermedia* introduced by Messrs. Veitch from the Philippines, and named by Lindley in 1853.

PLEUROTHALLIS SCAPHA.—There are about four hundred species of *Pleurothallis*, and there are not four that are considered worthy of cultivation. I know three—*Pleurothallis Roezlii*, *P. insignis* and *P. scapha*. The first named of this trio has nodding racemes of purple-red flowers, each over an inch long, and has been in cultivation about ten years. *P. insignis*, which differs from *P. scapha* only in having a bearded lip, first flowered at Kew in 1887. *P. scapha* was named by Reichenbach in 1874 from a plant in the collection of the late Mr. John Day. There is a good example of it in flower now in the cool Orchid-house at Kew. This plant is about a foot high, with ovate oblong leaf-blades and slender scapes, from six to nine inches long each, bearing five to seven flowers, which are remarkable for the length of their filiform segments; they are three inches long, and colored dull creamy white, tinged and streaked with dull crimson. The lip is small, glabrous, with the lateral lobes curiously twisted over the front lobe. It is difficult to describe the flowers intelligibly, but they may be said to resemble the insect known as daddy-long-legs.

VANDA KIMBALLIANA.—There is an illustration of an exceptionally well-flowered group of this fine *Vanda* in *The Gardeners' Chronicle* this week, and it teaches a lesson worthy of the attention of the Orchid-grower who does not know that this plant does best when grown in a cool house. In Messrs. Low & Co.'s nursery at Clapton, where it is grown in quantity and grown well, it is placed along with *Odontoglossum crispum*, except during winter, when it is put into a Cattleya house. If treated as a tropical Orchid it soon succumbs to thrips and damp. The grower of the group of plants mentioned above, Major Mason, says he grows them at the coolest end of a warm house in baskets suspended near the roof glass. They are planted in sphagnum and crocks and they grow in a marvelous manner. It is one of the handsomest of the smaller species of *Vanda*. It has subcylindric leaves and scapes a foot or more long, bearing from six to twelve flowers, each two inches across, white, with an amethyst lip.

CYPRIPEDIUM HENRY GRAVES was exhibited at the last meeting of the Royal Horticultural Society, having been brought in flower by Mr. Dimmock from Mr. Graves' garden in New Jersey, where it was raised from *C. Lawrencianum* crossed with *C. Marshallianum*. It obtained an award of merit on account of the singular form of its dorsal sepal and its color, which is apricot-yellow, with rosy dots. *Cypripedium* Mrs. Fred. Hardy, a hybrid between *C. superbiens* and *C. bellatulum*; Madame G. Truffaut, a hybrid between *C. ciliolare* and *C. Stonei*; and *Cypripedium* J. H. Berry, from *C. Harrisianum* and *C. concolor*, were exhibited by Messrs. F. Sander & Co., the raisers, and were considered worthy of the award of merit. Two other certificated hybrid Cypripediums, shown by Messrs. J. Veitch & Sons, were *C. mimoso superba*, raised from *C. Spicerianum* and *C. Arthurianum*, and *C. Norma*, a hybrid between *C. Niobe*

and *C. Spicerianum*. These "pedigree" Orchids are nuisances, in a literary sense at any rate.

LÆLIA PURPURATA.—This Orchid must be still growing in immense quantities in its haunts, the woods of Santa Catharina, for, during the last twenty years at any rate, it has been imported by myriads, and still they come. Next week one nursery firm offers to sell by auction "seventy cases of *L. purpurata*, large plants in grand condition," and another offers one thousand grand masses of it to be sold without reserve. A good variety of this *Lælia* is a superb Orchid, but it varies a great deal, and one too often meets with forms that are thin and spidery in form and poor in color.

LÆLIA AUTUMNALIS is also very abundant in England now, large importations of it having recently arrived. I saw thousands of fine, healthy masses of it in a nursery near London a few weeks ago. This, too, is an Orchid of great merit; indeed, it and its ally, *L. anceps*, are unsurpassed in the genus, considering them from all points. They are easily grown, they flower freely and their flowers are beautiful.

WILLIAM THOMPSON, the famous Scotch gardener, nurseryman, and author of several classical horticultural works, died on the 12th ult. at Clovenfords, after a short illness brought on by a fall. He was in his eighty-first year. Thompson, of Clovenfords, formerly Thompson, of Dalkeith, was as prominent a figure in the horticultural world as Hooker, of Kew, or Gray, of Harvard, in the realms of botany. To quote from the editorial notice in *The Gardeners' Chronicle*, "He was a prince among gardeners, of stately mien, and of great tact, using his influence at all times for the advancement of gardeners and gardening. He was a man of strong common sense, thoroughly practical in all his ways and his teachings." He worked in private gardens till 1871, when he started as a nurseryman at Clovenfords, where he grew grapes largely, and latterly Orchids. His book, *A Practical Treatise on the Cultivation of the Grape-vine*, is a standard work with vine-growers.

New or Little-known Plants.

Gunnera manicata.

ENGLISH horticulturists who have an eye for noble foliage-plants available for outdoor effects do not fail to make use of the two big-leaved *Gunneras*, namely, *G. scabra* and *G. manicata*. They are not exactly hardy here, except in the warmer parts of the country, for even at Kew they require protection in severe weather and from cold winds in spring. But in such favored places as the south of Ireland, South Wales, Devon and Cornwall, they are quite at home and grow to an enormous size.

The view represented in the accompanying picture is in the garden of Mr. Pendennis Vivian, at St. Martin, Cornwall. The value of the *Gunnera* in the garden is here shown exceedingly well. Nothing could be finer than the effect it produces by the side of a lake with *Arundo*, *Gynerium*, Bamboo, *Richardia* and other moisture-loving plants as its companions.

Mr. Vivian writes that the *Gunnera* was twelve feet high when the photograph was taken, and as the leaves are probably fully ten feet in diameter, the magnificent appearance of this specimen, in its beautiful setting of feathery foliage, is easily imagined. I have seen great masses of this *Gunnera* in some parts of Ireland, where the leaf-stalks were high enough to enable a tall man to walk erect among them without touching the blades. In the garden of the late Sir George Macleay, at Pendell Court, in Surrey, there used to be a very fine specimen of it growing on the edge of the lawn, where it dipped to the lake. *Gunneras* must be planted in such a position if they are to do well. A sheltered place, near water, where the soil is deep and rich, and where the sun can shine upon the plant all day is the right position for both *G. manicata* and *G. scabra*.

The history of *Gunnera manicata* was told by Mr. J. G. Baker in the *Gardeners' Chronicle* in 1886. It was discov-

ered in southern Brazil by Libon in 1865 and distributed by Linden, the Belgian nurseryman, in 1867.

It differs from *Gunnera scabra*, which is a native of Chili and Bolivia, in being more robust, with broader, more elegant and more spiny leaves and in having much taller flower-spikes. Where there is room for both, both are worth growing, but if only one *Gunnera* is wanted, then *G. manicata* is to be preferred. According to Mr. Baker, *G. chilensis* is an older name for the plant generally known as *G. scabra*, which has been in cultivation since 1849. I have seen the Kew specimen of this a mass of big leaves fifteen feet through and eight feet high, the leaf-blades being over four feet across. This, however, is dwarfed by a specimen of *G. manicata* seen by Mr. Burbidge in County

on the high mountains of Imeretia, in upper Mangrelea, and other parts of the Orient, where it replaces the Spruce of central and northern Europe, and often forms vast forests. From other Spruce-trees it may be distinguished by its more slender branches and by their dark green crowded leaves that cover them. The habit of cultivated trees as they appear in this country is particularly graceful and attractive; the long upward sweep of the lower branches and the spray-like branchlets standing out freely from the dark body of the tree and allowing opportunity for a free play of lights and shadows, give a charm to the Oriental Spruce which no other hardy Spruce-tree possesses, and at once attracts the eye and excites the imagination. The first Oriental Spruces planted in the United States are thirty

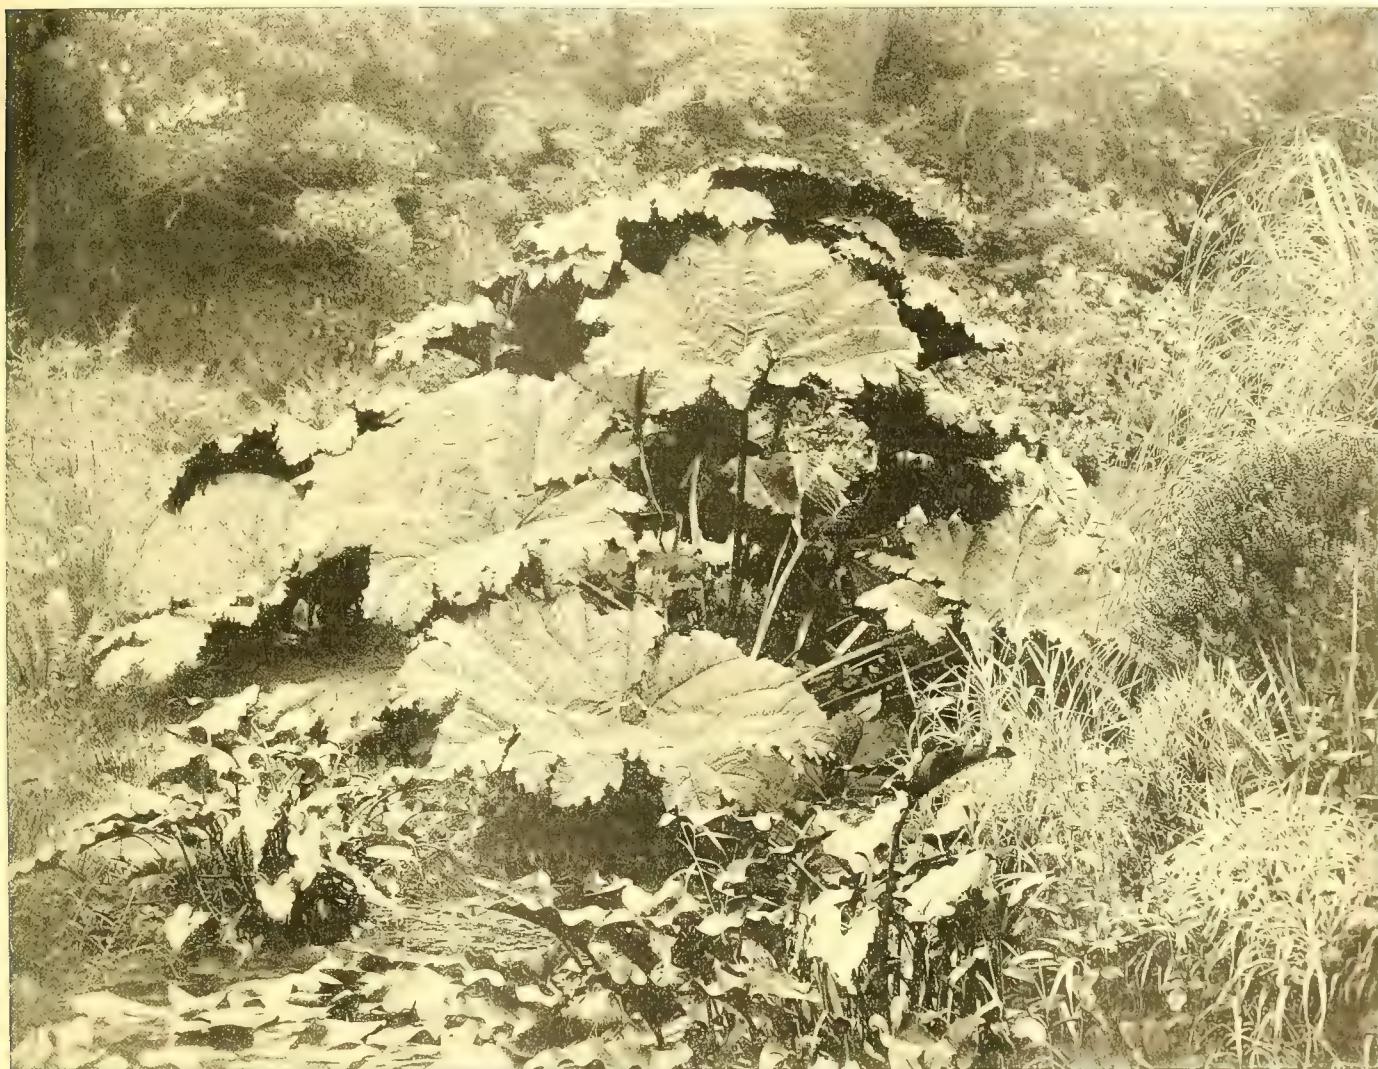

Fig. 8.—*Gunnera manicata*, in Cornwall, England.—See page 54.

Down, Ireland, which had twenty-five leaves, the stalks as thick as a man's arm and six feet high, the diameter of the whole being thirty-five feet, that of the largest leaf-blade ten feet three inches. In Guernsey there is a long ravine through which a stream runs, and which is entirely filled with this *Gunnera*, it having become naturalized there.

London.

Plant Notes.

PICEA ORIENTALIS.—Of the evergreen trees from foreign countries that have been planted in the northern Atlantic states, no other, perhaps, is so full of promise as a permanent inhabitant of our parks and gardens as this species. The Oriental Spruce is a large and common tree in many countries adjacent to the Black Sea, or the Anti-Lebanon,

or forty years old, and are now more than fifty feet tall, so that while we do not know it yet in its adult state, and cannot determine whether old trees will be as beautiful and satisfactory as young ones have proved to be, it is safe to say that this tree is perfectly hardy from Boston to Philadelphia, and that it will retain its beauty for half a century at least. Of rather less rapid growth than the Norway Spruce and several of our American species, it is particularly suited to decorate lawns and small pleasure-grounds, and it is remarkable that it is so little known and so rarely planted. Good specimens of the Oriental Spruce can be seen in Central Park in this city, and there are several unusually fine ones in Prospect Park, Brooklyn. One of the oldest and best of these trees in the country stands on the grounds of Mrs. Rufus Leavitt, at Flushing, Long Island, and, of course, there are good trees in the collection of Mr.

Josiah Hoopes, at West Chester, Pennsylvania; at Wodenethe, Fishkill-on-Hudson, and in Mr. Hunnewell's Pine-tum at Wellesley, Massachusetts.

HIBISCUS SYRIACUS.—The best forms of this interesting and very variable shrub are not always planted in gardens. Many of the forms seen in northern gardens are those with double or semi-double flowers of mixed colors. These are somewhat more lasting than the single-flowered varieties if the length of time that individual flowers remain in good showy condition is considered. The single-flowered original species and its single varieties are, however, much more desirable, as they are more purely beautiful. The species varies greatly in the color of its flowers, there being white, purple, red and other shades; one of the most interesting has large rosy purple flowers with a crimson centre. These single-flowering plants bear seed in abundance, but it often does not mature well in northern gardens. Seedlings of varieties show some variation, especially where several kinds are growing together, but as a rule a particular variety will reproduce itself from seed. Where it is desired to get the exact counterpart of some particular plant it is best to propagate by layers, by cuttings of green wood taken in right condition in July, or by cuttings of ripe wood taken in the autumn or winter, and stored in moist sand, and started either in the greenhouse or open air. In localities where the Hibiscus is not very hardy it may be planted with the main roots in two opposite directions, and in the autumn the soil at one side of the stem may be removed and the plant bent at right angles to the line of the roots and covered with soil if necessary. Or it can be grown in a tub, and be transferred to the pit or cellar in winter. The greatest horticultural merit of these plants rests in the fact that they are showy late-summer bloomers, keep up a succession of flowers for a long time and thrive in a city atmosphere where many other kinds of shrubs would fail. They will flourish in a great variety of soils and in cold climates, but do best in a dry, rather than a wet, situation.

CLEMATIS INDIVISA.—We have lately seen long flower-covered stems of this plant used with charming effect in the decoration of the walls of a ballroom. An inhabitant of New Zealand, where it festoons trees and shrubs on the borders of the forest, *Clematis indivisa* must be grown in the northern states in a cool greenhouse, and succeeds best when planted in a border of well-drained soil and allowed plenty of head-room in which to produce its long flexible branches, which are covered in January or February with axillary panicles, often a foot in length, of flowers two inches or more in diameter when expanded. The beauty of their creamy white sepals is enhanced by contrast with the bright yellow filaments and purple anthers of the stamens. The plant ought to be a real addition to California gardens, where it is probably known, and eastern florists with large houses at command might grow it advantageously for festal decoration, which every year in all American cities makes larger calls upon their skill, resources and taste. An illustration of this plant was given in this journal (vol. vi., page 167).

CYPripedium SALLIERI ROEBLINGII.—As long ago as 1878 a hybrid obtained by fertilizing *Cypripedium villosum* with the pollen of *C. insigne* Maulei flowered in England, the cross having been made by Mr. Seden, who succeeded Dominy at this work in the Veitchian Nurseries. Seven years later, or in 1885, another hybrid between *C. villosum* and *C. insigne* was raised by Monsieur Godefroy Lebeuf, of Argenteuil, and was named *C. Sallieri*. According to the laws of nomenclature which now prevail, *C. Sallieri* ought to rank as a variety of *C. nitens*. Among the other hybrids obtained by crossing different varieties of these two species the one noted above is conspicuous for its beauty. The seed parent was a fine variety of *C. villosum*, and the pollen parent was the variety *Amesianum* of *C. insigne*. The seed was sown at the United States Nurseries on the second of October, 1890, and it first flowered in November, 1894. The plant has a bold habit, with dark

lanceolate leaves about nine inches long and one and a half inches across. The dorsal sepal is large, elongated, recurved at the base. The upper part is white, and the lower portion is yellow, heavily marked and spotted with purple-brown. The petals and pouch are a brownish yellow, the staminode is a bright golden yellow. It seems altogether a very desirable plant, and has been named in honor of C. G. Roebling, Esq., of Trenton, New Jersey.

Cultural Department.

Treatment of Amaryllis.

IN visits to other gardens it is noticeable that the Amaryllis or Hippeastrum is more generally cultivated than heretofore. This is not surprising when one considers how easily they are grown, and the great improvement that has taken place of recent years in such strains as are sent out by Messrs. Veitch and others. Some visitors who were here recently were most enthusiastic in their praise of the display of Hippeastrums at the Chelsea Nurseries. The question was asked if they did not take a great deal of heat, and it was a surprise to them to find in the coolest house over one hundred flowering bulbs that had been raised from the strain they had admired when in London. We are trying a few this winter in the cellar to see whether it is possible to keep them there when at rest, and the experiment so far seems a success. If they can be kept in a cool cellar after the foliage has died off it will be a great gain of storage-room in the greenhouse.

It has been noted previously that the best way to obtain a good strain of Hippeastrum is to sow seed as soon as it can be had fresh, which is in August. As the germinating power is soon lost, it is best to wait until fresh seed is harvested, when it should be sown as soon as it arrives. If this has already been done, the young bulbs must be grown on without any check until they are two years old. The foliage will then dry off naturally, and the bulbs will be best kept perfectly dry, until there are signs of growth in the early months of the year. We have already picked out a few that were starting to throw up flower-spikes, but the majority of them are still at rest, and will remain so as long as we can keep them dormant, for we want them most during May and later.

After the bulbs reach flowering strength they are as truly deciduous as a Hyacinth, losing both foliage and roots each year. They must of necessity be potted in new soil as soon as signs of growth commence, to avoid check to the young roots just starting out. After potting, a warm greenhouse is all that is needed to keep them growing until the warmer days of spring have come. After flowering we put them in a frame out-of-doors to mature the growth, and give them all the sun and air in summer, since, being natives of South America, our sun in summer is not too much for them, and serves well to ripen and insure a good bloom the next year. It will be seen that it is necessary to grow these bulbs in the greenhouse on stages for three or four months only; the space occupied during that time is not such a great consideration when we take into account the decorative uses of the plants when in bloom. The most suitable soil is one that is rich and porous; we use charcoal freely, and loam, leaf-mold and a little manure, preferably that from the sheep-pasture, seems to suit them best. The bulbs should be potted in the soil to about half of their depth, leaving the upper half uncovered.

Thrips are the only enemies of these plants that seem to trouble the cultivator, and their ravages are soon apparent by the red color of the under sides of the foliage. We use Fir-tree oil to spray with when it is too late to apply tobacco-dust as a preventive; but it is best to keep a sharp watch and take this pest in time, when tobacco will be found an effective remedy.

Amaryllis aulica has been used as one of the parents of some of the garden Amaryllis, with the result of a tendency in the plants to be evergreen. This is a disadvantage if the bulbs have to be stored under the benches, as these need a good light in winter. Many of the evergreen sorts are good, but they are excelled by those that have been obtained from the deciduous species, such as *Hippeastrum vittatum*, *H. equestre* and *H. reticulatum*.

It is too often the case that a plant after it has bloomed is put in some out-of-the-way corner, and left there until the time comes to store it for the winter. But a glance at the bulbs after they have flowered will show that they are shrunken to about half their normal size, indicating loss of tissue. To replace this the plants should be plunged into some material

to keep the roots cool and moist until the time comes to dry them off in fall. A spent hot-bed, old mushroom-bed material, or even leaf-mold, answers well, and there is not so much labor needed to water when the pots are plunged.

We find that very few bulbs need a pot larger than six inches. The young offsets that form after the bulb reaches the flowering size are taken off at each annual potting when they are large enough. Several of these are put in a pot and grown on until they are large enough to bloom. Sometimes an unusually large bulb is put into a seven-inch pot, but the majority are grown in the smaller size, which is sufficiently large and more easily handled than are the larger pots.

South Lancaster, Mass.

E. O. Orpet.

Sweet Potatoes from Slip Seed.

IN many parts of the southern states the growers of Irish potatoes find that they have the best success with that crop when second-crop seed is used. The potatoes are planted early in the season, and when mature the tubers are planted and a second crop produced. This second crop, which matures late in the fall, is in great demand for planting the following season, as the tubers produce strong, healthy plants, which yield much more abundantly than do those of the first crop when kept over for seed.

Growers of sweet potatoes in Virginia find that by using what is known as "slip seed" they are able to secure a much larger crop of roots, which are of much better quality than those from the sets ordinarily used. It is also claimed that the use of slip seed produces crops that are free from injury by the disease known as black shank.

Slip seed is grown from cuttings about six inches long taken during the latter part of June or the first of July from the vines in the fields. These cuttings are at once planted in the same manner as are the rooted plants which are used earlier in the season for the main crop. The cuttings produce tubers which compare favorably in size and yield with those grown from sets, and when used as "seed" these tubers produce a greater number of stronger and healthier plants than those grown from rooted plants earlier in the season. The demand for this seed is increasing every year, and the production of this slip seed is becoming quite an industry in many sections.

Experiment Station, Newark, Del.

M. H. Beckwith.

Chinese Primroses.

FOR the past two years we have grown for trial and selection a collection of Sutton's well-known strain of Primulas. Each year we have made notes of the kinds as they flowered, so that the best could be selected for our purpose, both as to boldness of stem, large flowers, good colors, and, most important of all, good habit of growth. The first thing noticeable was the failure of the double-flowered kinds to come up to the required standard. The flowers were of good colors, double, and free-blooming, but there was not that individuality about them that we get in the good strains of single flowers. Their use as decorative plants was of correspondingly less value, and we shall in future grow no more of them. Another defect in the so-called giant strains was the sacrifice of other points to the production of very large flowers. The foliage was in nearly every instance coarse and ill-balanced, and the stems rarely carried the flowers erect as in the other strains, owing to their abnormal size.

Of the other sorts we have, however, selected a few that seem to be as near perfection as it is possible to get them. It used to be a recognized fact that Primulas with leaves and stalks of a red tint were sure to bear colored flowers, but this is changed now, and some that have red stems produce pure white flowers of sterling merit. At the top of the list we place Sutton's Purity. This sort has Fern-leaf foliage of a dark purple hue that sets off the large pure white flowers to great advantage. I have never seen flowers of any Primula that can compare with this kind for size, substance and purity, and we shall grow no other white variety, except a few plants of Pearl; the latter is a fine selection of the old variety *Alba magnifica*, and has similarly green foliage. The pink colors we have sifted down to Rosy Queen, a Fern-leaf, compact-growing and very free-flowering variety that has flowers the color of the Grace Wilder Carnation. It has entirely superseded the older and well-known Reading Pink, owing to its delicacy of color and free growth. Reading Blue is still the best Primula of that shade, and it is of a more decided lavender-blue each year. We have never had this sort so good as during the present season, owing, perhaps, to the cooler temperature in which it was grown. We find that a temperature of forty-five to fifty

degrees is better than a higher temperature for the full development of the rich colors and to give substance to the flowers. For a good scarlet we have selected Reading Scarlet as one of the most reliable and the richest-colored. It has, however, the tendency to come into flower early in the fall, and we, therefore, sow it a month later than the other kinds, say at the end of April. The other sorts are sown in March, except the blue one, which is more delicate in constitution and takes longer to develop. It may be sown in January, or early in February, if large plants are desired for next fall.

There are few winter-blooming plants that give more satisfaction than Chinese Primroses, whether for conservatory or house decoration, if a good strain of seeds can be had. Choice Primulas are no more difficult to grow than poor ones, and take no more time and care. We use a light, rich soil at all times, making it a little richer at each potting, until the plants are in the pots they are to flower in. A five-inch pot will produce a good plant, but a size larger is preferable, and if very large plants are required an eight-inch pot can easily be filled by the larger ones before winter sets in. Primulas sometimes get what the older gardeners call water-pot fever; their susceptibility to overwatering is the only drawback to their cultivation, but this is easily overcome by a little care. A slight shade is necessary in the hot months of summer, and plenty of air while the nights keep warm.

South Lancaster, Mass.

E. O. Orpet.

Meetings of Societies.

Nebraska State Horticultural Society.—II.

WE continue our report of the annual meeting of this society by giving abstracts of a few of the addresses and discussions on the cultivation of Cherries and Plums.

THE CULTIVATION OF PLUMS.

Mr. E. S. Hartley's experience with this fruit may be summed up as follows: "The first crop I marketed paid the entire cost of my Plum orchard up to that date." He thought that this fruit offered a more promising field for experiment than most other branches of pomology. He had fruited two hundred seedlings, and the result showed a marked tendency among American Plums to vary. We give condensed extracts from Mr. Hartley's address:

In 1888 I planted 240 trees, but many of them were untrue to name, and therefore my venture has proved less satisfactory than it should have been. However, 140 trees bore full crops last season, six years after planting, and we marketed them at an average price of \$1.50 a bushel, or at the rate of \$150 an acre. Plum pockets began to appear about the time of blossoming, but these were hand-picked and burned. Sprouts were gotten rid of by horse-power, an attachment having been made for the cultivator which shaved them off about an inch and a half or two inches below the surface. By another device the plums were conveyed to the marketing boxes without touching them with the hands, the whole crop of a tree being transferred to the boxes in about ten minutes. This device consisted of a canvas buttoned about the tree into which the plums were shaken somewhat on the principle of the Cook apple-harvester.

One of the chief difficulties in estimating the value of new varieties is to determine the influence of the stock upon the cion, which seems to be very marked in the case of the Plum, both in the quality of the fruit and the abundance of the product. For instance, De Soto on Miner stock has proved weak and barren, and seems to lack nutrition. The same variety on roots of *Prunus Americana* is very productive, and a healthier tree. Varieties of *Americana* and *Chickasaw* have been reported to do well on Peach stocks. Myrobalan, Marianna and the Sand Cherry, as stocks, are alternately praised and condemned, according to the cions which are put into them. For this reason it seems necessary to plant the same Plums on different stocks until their effect is better understood.

The improvement of the native Plums is still in its infancy, as compared with the development of other fruits. I believe the possibilities here are very great, both in the improvement by selection, natural pollination and artificial hybridizing between native varieties and European and Japanese varieties. The time is not far distant when the plum will outrank the cherry as a useful and popular fruit, and rival the peach and pear in popularity. We are in a region specially favorable for the development and growth of the Plum. The seasons of 1893 and 1894 have demonstrated the ability of the Plum to withstand drought exceptionally well. The driest year known in this section of the country has produced the largest crop of

plums. In the effort to improve our Plums by cross-breeding we will doubtless achieve better results by resorting to the Japanese varieties, since they possess some desirable characteristics which the European Plums do not, particularly vigor and productiveness. So far as tested, these Japanese varieties give satisfaction in the west. Some of them have withstood a temperature of thirty-seven degrees below zero at Geneva, Nebraska, without the slightest injury. By watching them side by side with our hardy natives the past four years and witnessing their splendid behavior, I have been forced to the conclusion that there is a close relation between our natives and these Japanese introductions. In their large size and fine qualities lie the condensed improvements brought about by, perhaps, thousands of years of selection, while our natives have been left to improve under the operation of the law of "the survival of the fittest."

In the discussion that followed, Professor Hansen, of the Iowa Agricultural College, called attention to the fact that the Japanese varieties bloom so early that they are often caught by a frost which other varieties may escape. Burbank is the hardiest Japanese variety at Ames. Of the east European varieties, Moldovka and Voronesh Yellow are doing finely. Wyant is the most reliable native sort. At the college they propagate all Pears and Plums by side-grafting at the collar during the winter.

Mr. Masters called attention to the fact that the budding season of the Americana stock can be lengthened by cutting off about half of the top when the bark begins to set. Then, when the new sprouts begin to start, the budding can be continued without difficulty. This point is important since one of the great objections to this stock is that its season of budding is so short. Nurserymen seem to agree that there is not a satisfactory stock for the Plum in general use, and they are anxiously waiting for something better than they now have.

EXPERIENCE WITH CHERRIES.

President F. F. Stephens stated that he had planted somewhat freely for the last twenty years, and had not succeeded in raising a bushel of sweet cherries, though he had planted a great many varieties. Napoleon Bigarreau has seemed the healthiest of the sweet varieties, but only one tree remains sound, and, while that blossoms freely, it has not yielded fruit, though the tree is five or six inches in diameter. Neither have the Dukes given success, although the May Duke has come near to succeeding. These trees remained alive till they were six inches in diameter, but the birds invariably gathered the fruit. They are at work earlier in the morning than he is, and begin to pick as soon as the fruit colors. The gentleman of leisure may protect his fruit by covering the tree with netting, but whether this will ever pay on a commercial scale at Nebraska prices is doubtful. It seems wiser to plant enough for the birds, our neighbors and ourselves, and this planting should be of varieties that yield abundantly and ripen in a comparatively short time. In 1891, in Mr. Stephens' orchard, it took 100 bushels to feed the pickers and the birds, or one-eighth of his crop of 800 bushels, yet he dare not dispense with the birds lest a worse trouble come upon him, for in the rapid increase of insects the birds will doubtless fully repay for the toll they take from our fruits.

In varieties the Early Richmond easily leads all others. The quality of Late Richmond is good, but it fails in productiveness. In place of this the large Montmorency is recommended, with the Osheim and English Morello. The latter, however, like all late cherries, is less desirable, owing to its longer ripening period and consequent greater injury from birds. The Russian varieties seem to be open to the same objection, and, in addition, are lighter yielders. They are harder in tree and bud, however, and may prove valuable for the north-western part of the state. The Vladimir cherries reproduce themselves from seed, and are likely to prove valuable in especially trying localities.

Good growth and abundant feeding make a marked difference in the quality of the fruit. Even the Early Richmond, when receiving high cultivation, and heavy manuring after it comes into bearing freely, becomes a larger and much richer cherry, and would hardly be recognized as the Early Richmond. Deep plowing before planting, steady surface cultivation in the orchard and heavy surface manuring after the trees come into bearing will improve any of our varieties in a surprising degree.

Mr. D. N. Reed, of Blue Springs, Nebraska, has a Cherry orchard of seventy-four trees. The first Richmonds ripened about June 1st, and a crop of 2,160 quarts was marketed from

fifty-four trees, or an average of forty quarts a tree. The remainder of the orchard gave an average of thirty quarts a tree, making the total yield from the seventy-four trees 2,660 quarts, which found a ready sale at eight and one-third cents a quart, or \$212.80. One acre planted to Cherry-trees sixteen feet apart requires 170 trees, and, using the yield for 1894, would give in value \$488.75 an acre. With the varieties now fruiting Mr. Reed has ripe fruit on the trees for about two months. The best variety in quality, by all odds, is the one supposed to be Early Morello. This ripens three or four days after the first Early Richmond; is a black cherry; meat and stone colored red to the seed. It commands a ready sale, customers asking for the black cherry. The tree is a good grower and as prolific as Early Richmond, and fully as hardy on our grounds. Next in quality and season is Large Montmorency, closing up the gap between Early Richmond and English Morello. This is a better cherry for eating from the tree than Early Richmond; as good a grower and as prolific. Mr. Reed also finds this fruit to respond quite as promptly to good cultivation as any other fruit, and more certainly than most fruits. The last two summers have proved—in Nebraska and Iowa, at least—that orchards must be cultivated to keep in health, and thus get growth of wood and fruit-buds; for without wood-growth there will be but few buds. That cultivation is the next thing to rain was demonstrated in many instances last year.

Mr. Peter Youngers said that by planting Dye House, Early Richmond, Early Morello, Large Montmorency, Osheim, English Morello and Wragg a constant succession of fruit may be obtained in Nebraska from June 5th to August 5th—two full months of ripe cherries. This list, compared with one made in 1874, is remarkable; at that time the Early Richmond was the only Cherry considered safe to plant. But the cause of horticulture has advanced in twenty years until, instead of one variety, two full months of this wholesome fruit can be had. And with the new additions from Russia and Germany, together with the new seedlings that are now in process of development, Mr. Youngers felt assured that the gain in the future would equal that of the past, and when the list of the best market sorts of cherries is called for twenty years from now it will cause the old members of the Nebraska Horticultural Society to feel that they were not born in the cherry age.

Professor Hansen considers the Mazzard to be far the best stock for the Cherry, notwithstanding the fact that the Mahaleb is the one almost wholly used throughout the west. The cherries with colored juice, especially, do not succeed well on the Mahaleb stock. There seems to have been a general fear of the Mazzard stock on account of its sprouting, which is, perhaps, aided by the nurserymen, since they find the Mahaleb the most convenient stock to work. The Sand Cherry has proved a failure as a stock for the Cherry, but is a good stock for the Japanese Plums. It seems to be more closely allied to the Plums than to the Cherries.

Western New York Horticultural Society.—II.

THE following is a continuation of our report of the annual meeting of this society :

HOME-MIXED FERTILIZERS.

Dr. Caldwell, of Cornell University, in an address on this subject, said that a "cheap thing" in fertilizers was quite unsatisfactory as other cheap things. The composition of commercial fertilizers is usually given in per cent. Available fertility is rated by units in the trade, and a unit is twenty pounds, so that the figure denoting the per cent. gives us the number of units of the potash, phosphoric acid or nitrogen in a ton. The price of a unit is twenty times the price of a pound, which means for nitrogen \$3.50, for phosphoric acid \$1.30, and for potash \$1.00. Most of the cheaper grades of fertilizers are sold for more than they are worth, while the better grades are sold at their actual value, or a trifle under. In New Jersey last year 700 tons were home mixed at an average cost of \$29.70 a ton, and an average value of \$49.27. The farmers bought high-grade fertilizers intelligently, not hit or miss. The average cost of a pound of nitrogen, phosphoric acid and potash respectively, in the home-mixed fertilizers, was 14.9 cents, 5.7 cents and 4 cents, while in manufactured goods it cost 24.8 cents, 9.4 cents and 6.7 cents. The available food was 436 pounds to the ton in the home-made fertilizer, and only 299 pounds in the manufactured.

The manufacturer claims that he can do the mixing better than the farmer. The farmer can buy the goods ground as finely as he wants and mix them as thoroughly as the manufacturer, as is shown by the comparison of twelve samples of manufactured articles with ten of home-mixed. The impor-

tance of thorough mixing depends on the solubility of the plant-food. If the water dissolves it as soon as it goes into the soil, then that distributes it more efficiently than can be done in any other way. This solubility affects the nitrogen most, and this is the constituent which the manufacturers claim they can furnish in better condition than the farmers can. In the home-made fertilizers seventy-two per cent. of the nitrogen was available, while only twenty-eight per cent. was available in the manufactured fertilizers. Of the home-mixed material only twenty-eight per cent. needed to be made fine and mixed thoroughly, while in the manufactured article seventy-two per cent. required such treatment. Sixty per cent. of the price of average fertilizers is paid for nitrogen. By the proper growing of certain Leguminous crops much of this may be saved.

The farmers of New Jersey who have been doing so much of this home-mixing feel satisfied that the results are better and cost less than their former practice. Of course, each man must experiment on his own land by excluding one plant nutrient and thus ask if his land wants this, that or the other of these three important constituents. It is bad practice to be stingy with applications of fertilizers. It should be remembered that there are three and a half million pounds of soil on an acre, taking one foot in depth, and then one can estimate how small an amount of food 700 pounds to 1,000 pounds of fertilizer will furnish when it contains only five per cent. of nitrogen, ten to fifteen per cent. of phosphoric acid, and ten per cent. of potash.

THE EVOLUTION OF TILLAGE.

Professor Bailey began his address on this subject with the statement that tillage, as we understand it, was not known till two hundred or three hundred years ago. The physical necessities of killing weeds, putting in the seeds and getting the crops out was all that was aimed at. Two hundred years ago Tull observed the tillage of vineyards in the south of France, and as a result published a book in 1733 known as *Horse-hoeing Husbandry*. His theories were that by tillage soils might be forever reinvigorated and renewed. Some thought the necessary elements for plant-growth were nitre, water, air, fire and earth. Tull ruled out the air. He said that the plant is earth. He thought they fed on earth, and hence it was necessary that it should be finely divided, so it might be taken up by the mouths of the roots. The value of ashes was entirely due to their fineness. He observed also that tillage made the soil moist. He thought the moisture came from the air.

We have now learned to till for the sake of tillage. At Cornell, Tull's system of growing Wheat in rows and cultivating has been followed by taking a piece of ground and dividing it into strips five and a half feet wide and planting alternate strips each year with Wheat, and keeping the vacant land cultivated. The result is as heavy crops as the average ones of New York state the last five years on the same piece of ground.

By failing to cultivate well, farmers are borrowing money when they already have a lot in bank not drawing interest.

The failure of apples is due to the neglect orchardists have shown for the last twenty-five years, and now they are reaping the harvest. They should use the deposit in the bank first; get the most possible out of the land by tillage. Some hold three or four years of such treatment to mean failure afterward. But we need not expect to correct the wrongs of a quarter of a century in three or four years. Nine-tenths of all the orchards in New York are in grass, and half of these yield annual crops of hay. We are hunting fungi with spray guns and forget to feed our crop-producers. If an orchard is worth planting it is worth caring for.

It is impossible to begin cultivating an old orchard because the roots have come to the surface. In Erie County, on a light soil, one grower had plenty of berries in a dry year by keeping the soil in good condition by cultivation. He held the moisture from the rains by constant cultivating so as to interrupt and break the capillaries which drew the soil-water to the surface, where it evaporated and was lost, and at the same time he spread over the land a porous blanket two or three inches thick. In the Pecos Valley, now becoming famous, the yearly rainfall is five or six inches, but they keep it all by cultivation, and yet here we are complaining of trees shriveling and drying up with forty-eight inches rainfall.

All the growth of an orchard should be made by August. The rule should be to begin early, plow deep, and follow rains closely with a cultivator. He had found roots of two-year-old Plum-trees eight feet from the trunk, while the top only extended four feet, thus showing that the root extended farther than the top. In the early part of the season the tree-roots

catch food, while later the trees should be checked by Crimson Clover, which takes the available food and moisture, and gathers food into a better shape for trees. It should be sown in August, but it ought to be either long before or after the fruit is gathered.

Pruning is a means of tillage; it concentrates food in a short space. After all this has been done, then spray. When an orchard in sod is doing well it merely shows that the land there has superabundant fertility. Half of the old orchards should be cut down. Those which cannot be plowed should be dragged and have an application of 500 pounds of superphosphate and half as much potassium chloride to the acre. Feed the crops, not the land; apply 200 pounds every year, not half a ton every five years.

In the discussion which followed this paper, Mr. Tabor suggested that cultivation may stimulate the production of trees, rather than of fruit, tending to push the tree with the greater amount of nitrogen it secured as food. An orchard in Dutchess County was thoroughly cultivated and dressed with 1,500 pounds of bone and 500 pounds potassium chloride. Another had a good dressing of stable-manure. The orchard treated with potash and bone gave glossy, firm, high-colored apples, while the one dressed with barnyard-manure gave larger, but less highly colored, apples, which shrank more, and did not carry to England as well. He thought the nitrogenous manure keeps the wood growing late, so that it does not ripen well, and immature buds mean poor fruit. To this Professor Bailey replied that he would supply potash and phosphoric acid, but would not buy nitrogen. Sometimes, when lands are rich in nitrogen, and an orchard is too rankly growing, then seeding it down to grass might be its salvation. This, however, is a special case; as a rule, cultivation is better than grass.

A THOUSAND DOLLARS AN ACRE FROM BLACKBERRIES.

This was the rather startling title of a paper read by Mr. C. E. Chapman, of Peru. In recounting his experience Mr. Chapman said that he had heard that Blackberries would grow anywhere, and he, therefore, bought some plants of Kittatinny, took no particular pains to set them, and many died. He used on the ground a quantity of raw, coarse manure, and the next year many of the canes broke. He then concluded that to grow Blackberries required some study. As a result of the study he prepared a piece of chestnut loam, put it in prime condition, bought some plants of Agawam and Snyder from good, careful growers, at prices that would warrant him in expecting good plants. He set them carefully in trenches seven feet apart and eight inches deep in the trench. He found these varieties deep-rooted and thrifty, and where mulched, pruned and not fed too much raw manure he had little trouble from winter-killing. When setting his plantation he applied eight hundred pounds of potash to the acre. He was careful to have all plants well set, and he frequently clipped the tops. All weak canes were cut out. Every spring he applies a light dressing of commercial fertilizer. Immediately after fruiting he cuts out and destroys all the old canes, as these are the seat of nearly all the troubles of this fruit. During the winter he mulches heavily and leaves the mulch on late in the spring to prevent early starting.

Although he did not believe a thousand dollars an acre could be realized under ordinary conditions, yet this was an achievement worth striving for, and small patches had been made to yield at that rate. It required the right combination of man, soil, variety and cultivation, but it could be done.

Crimson Clover was much talked of at this meeting, as it always is nowadays at any gathering of farmers or fruit-growers, and it was suggested as the best crop to cover the ground in winter and catch nitrogen, because it will grow all through the winter and be ready to plow under in the spring. There is danger of its dying as far north as New York state, according to Professor Waite, who said it had been killed out near Washington by a temperature of six degrees below zero. This may have been due, however, to the warm weather preceding it. Professor Bailey said it had not been winter-killed in New York during the last three years when raised from home-grown seed. Dr. Caldwell spoke of it as a quick-meal crop, and valuable because it worked when nothing else could, and his advice was to secure nitrogen by some leguminous crops, and apply phosphoric acid and potash, trying every possible combination. The nitrogen in dried blood or in bone-meal could be used any time in the year, but sodium nitrate could only be applied about the time of sowing or after a crop was under way, so that it could be taken up at once by the plants before it leached out and ran to waste.

Notes.

Between sixty thousand and seventy thousand bulbs of Japanese Lilies were disposed of at a single auction sale in London last month.

Mr. J. H. Hale writes to the *Florists' Exchange* of a new large winter pear in form like Vicar, but with a color as beautiful as that of the Bartlett and of quite as good flavor. The stock is owned by E. G. Mendenhall, Kinmundy, Illinois. A really first-class winter pear of this color and description would be a desirable acquisition.

A correspondent of the *Rural New Yorker* writes that after freezing weather set in last fall he planted all his Cauliflowers which had not headed in a trench and covered them with leaves. They continued to grow. Now the leaves are as green and crisp as they were in September, and every plant has formed a fine head. There seems to be no reason why Cabbage and Cauliflower which have not matured in autumn should be allowed to waste.

At the late meeting of the Royal Horticultural Society, in London, Mr. May's new Tea Rose, Mrs. Pierpont Morgan, which we have already described as a sport of Madame Cusin, received an award of merit. The fragrance of the flower was spoken of as one of its distinct features and as delightful as that of any Tea Rose known. It certainly speaks well for the flower that it preserved its fragrance after a journey across the Atlantic before it was exhibited.

At the late meeting of the American Pomological Society at Sacramento the Wilder silver medals were awarded: To the Coöperative Fruit Company of Newcastle, Placer County, California, for oranges, lemons, pomelos, Japanese persimmons, apples, figs and almonds; to the California Nursery Company, for sixteen varieties of olives on branches. Bronze medals were awarded to the Pioneer Land Company, Porterville, for ten varieties of oranges, pomelos and limes; to P. C. Drescher, of Palermo, for sixteen varieties of oranges; to the Horticultural Society of Sonoma, for Luther Burbank's improved nuts and other fruits.

An English traveler in northern Russia writes to the *Gardeners' Chronicle* that nothing surprised him more than the universal presence of well-grown flowering plants in dwelling-rooms. Even in the cells of monasteries and in the studios of city photographers farther north than Archangel he found such plants as Oleanders, Crotons, Pelargoniums and Fuchsias in almost every room. The double windows, so necessary to keep out the cold, have a draught-tight space between them filled with flowering plants, and it does not seem necessary to open them for air during the short hot summer. From September to June the country is buried in snow and shut in by ice. The average temperature for January is only ten degrees. The July temperature, however, has an average of sixty degrees, Fahrenheit, which is hardly to be wondered at when it is remembered that the sun shines twenty-two hours out of the twenty-four.

Mr. Thomas Meehan, in the last number of his *Monthly*, which contains a portrait of *Aquilegia Canadensis*, gives a very pretty description of a scene in spring along the Wissahickon, in which this wild Columbine was an important feature. It was twenty-five years ago, before the city, with its army of flower-gatherers, had crowded so far out into the country, when this plant was seen among the loose rocks at the base of a huge crag with blue Hepaticas, Spring Beauties and the snowy flowers of Blood-root mingled with the vivid color of the evergreen Fern, *Aspidium acrostichoides*. Up in the crevices of the crag *Corydalis glauca* was blooming profusely in the midst of tufts of common Polypody, while the trees and shrubs were just beginning to open their tender leaves, making a sort of half-shade which gives that peculiar charm to forest-scenery at this entrancing season of the year. The final charm to the scene was given by our wild Columbine, whose woody roots had descended deeply in the crevices of the rocks, where the leaves had been caught, to decay and make the rich food in which it delights. Why do not these plants make a nice list for a nook in some wild rock-garden for early spring effect?

We have heretofore given accounts of experiments to test the influence of electric light on plants growing in the greenhouse. The most important of these experiments were conducted by Professor Bailey, in which the arc lamp was used. In 1892 Professor Rane, of the West Virginia Agricultural Experiment Station, began some tests with incandescent lamps, although in the bulletin which recounts these experiments it is stated that in the arc light the chemical rays predominate, while in the incandescent light these are only slightly present,

and the supposition is that the light from an arc lamp contains properties which render it nearer sunlight in quality than that of the incandescent lamp. The results produced in the seasons of 1892 and 1893 were that the electric light had a marked effect on greenhouse plants, and appeared to be beneficial to such as are grown for their foliage, as, for example, Lettuce, which was earlier, weighed more and stood more erect. Flowering plants also blossomed earlier and continued in bloom longer under light, and most plants tended toward a taller growth. The influence of the light was objectionable in some plants, such as Spinach and Endive, as it forced them to run quickly to seed. The stronger the candle-power the more marked were the results.

Just now the stores of the retail florists are bright with an unusual number of cut flowers of different kinds, which show a wide variety of color. Single red tulips sell for \$1.00 a dozen, the more popular pink and yellow sorts commanding as much as \$1.25, while the double yellows cost \$1.50 a dozen, which is also the price asked for the few double pink tulips that have appeared. Other flowers of bulbous plants are single hyacinths at seventy-five cents a dozen, the limited supply of double hyacinths bringing thirty-five cents a stalk. Poet's narcissus are occasionally seen, and these sell for \$1.00 a dozen. Paper-white narcissus, yellow jonquils and freesias are seen in many collections. Well-grown lilacs, with luxuriant foliage, cost \$1.50 to \$2.00 for a bunch of ten to twelve single sprays for the purple flowers, and the white lilacs bring \$2.00 to \$3.00. The best carnations and a fair grade of mignonette cost \$1.50 a dozen. A bunch of two dozen sprays of forget-me-nots may be had for \$1.00, and half this quantity of lily-of-the-valley costs seventy-five cents. Roses are in great abundance, and vary in price, according to the quality, a great many of them being of more than average excellence. Good flowers of Madame Cusin bring \$2.00 a dozen, while the same grade of Bridesmaid, Bride, Catherine Mermet and Meteor sells for \$2.50 to \$3.00, and the better grades of any of these roses command \$5.00 and \$6.00 a dozen, and even more. American Beauties, with stems five feet long, bring \$1.00 apiece and upward. Cattleyas sell for \$9.00 a dozen and upward, and white varieties bring twice as much. Cypridiums are scarce, and cost \$4.00 to \$5.00 a dozen.

On page 344 of the last volume of this journal, Professor J. B. Smith, of New Jersey, gave an account of the way in which the San José scale was being brought into the eastern markets upon pears and, perhaps, on other fruits. In the last bulletin from the New Jersey Experiment Station, Professor Smith gives an account of the spread of this scale in New Jersey, where it was introduced upon Kelsey Plum-trees imported from California, and probably from Idaho Pear-stock received from western nurseries, and it has spread until it is known to have infested at least a hundred places in that state, and it is not safe to assume that it is absent from any orchard which has not been examined. This scale belongs to the group of armored scale insects, and a complete account of its life history and of its methods of spreading are given in this bulletin. Naturally it moves very slowly, but as it will crawl upon winged insects and the feet of birds, as well as upon ants, which are great travelers, it is sometimes carried great distances. It is probable that all Rosaceous plants will support the species, although it prefers some varieties to others. The recommendations in the bulletin are that every orchard set out during the last six years should be thoroughly examined, and if the scale is found to be present and confined to a few trees these trees should be taken out and destroyed, unless the infestation is slight, so that they can be gone over with a stiff brush and all the scales actually brushed off. In young orchards where the trees are not too large to handle it will pay to go over all the trees with a brush. Where the trees are too numerous or large they should be pruned back, removing as much wood as the tree can spare; the cuttings should be carted off and burned, and the tree should be washed with a potash solution. In California the insect is treated with gas which is formed by the action of diluted sulphuric acid on fused cyanide of potassium. This is not recommended for eastern orchards as the necessary outfit is too expensive, but wherever stock is infested in nurseries, or even suspected of infestation, all trees sent out should be made up in bundles with the roots wrapped to retain the moisture, covered with oiled canvas or other gas-tight material and fumigated for an hour, an ounce of cyanide to every one hundred and fifty cubic feet of space being used. This bulletin is worth careful study by all fruit-growers, since the San José scale is one of the most dangerous insects introduced into the eastern states within recent years, and no fruit-grower ought to consider the matter so unimportant that he can afford to neglect it.

The Red Cedar.

THE Red Cedar, which is not a Cedar at all in the botanical meaning of the word, but a Juniper, is one of the commonest and most widely distributed trees of North America. Indeed, it is not easy to recall any other coniferous tree which inhabits such an extended area, with the exception of another plant of the same genus, the *Juniperus communis*, found in various forms in all northern countries, and the great Siberian Spruce, *Picea obovata*, which ranges from the eastern borders of Russia to the Manchurian shores of the Pacific Ocean, and to central China. The Red Cedar is equally at home on the dry gravelly hills of New Brunswick and New England, on the northern shores of Georgian Bay, in the fertile valleys of Pennsylvania, on the limestone hills of eastern Kentucky and Tennessee, where it forms, with stunted shrubby growth, great forests or "Cedar Breaks"; in the swamps of the Florida peninsula, and on the rich bottom-lands of the Red River and its tributaries, where it grows to its greatest size. Less common in the west than in the east, the Red Cedar is apparently as much at home in one region as in the other; it is scattered over the eastern slopes of the Rocky Mountains of Colorado; and when the Mission of Santa Fé was established the Spanish priests might have seen it on the cliffs above the stream that enabled them to change a desert into a garden; it flourishes in northern Arizona, where the melting snows of the Rocky Mountains pour through the mighty chasm that divides the Colorado plateau, and it grows on the borders of lakes and streams in northern Montana and Idaho, and on Vancouver's Island.

The habit of the Red Cedar is as varied as the regions it inhabits. Sometimes it is bush-like, with many spreading stems, and at others it grows nearly a hundred feet tall, with a beautiful straight trunk four or five feet in diameter; sometimes all the branches are wide-spreading and form a symmetrical round-topped head; at others they are pressed close to the stem and the tree is pyramidal with a narrow spire-like top. These varieties of habit do not appear to be governed by any recognized conditions of environment. Often pyramidal trees grow side by side with round-topped or bushy ones, and in old age they all appear to lose their

pyramidal habit and to become round-topped. The pyramidal habit, however, is, perhaps, rather more marked and constant in fertile lands, such as are found in the valley of the Hudson River and in eastern Pennsylvania, than it is in New England, although pyramidal trees are common there. Of remarkable constitution and possessed of great powers of adaptability to varied climatic conditions, the Red Cedar only displays its full size and develops its greatest value in the warm and humid atmosphere of the south, and at the north and in the far west it looks as if it selected some particularly exposed and wind-swept hill for its home in order to show its toughness and indifference to the comforts of life.

The earliest European settlers on the Atlantic seaboard delighted in the Red Cedar, which reminded them of some inhabitant of their Old World gardens, and in its bright red fragrant wood which the Indians had known and valued before them; and the narratives of the old voyages and settlements usually describe the Cedar which was often included in the lists of treasures yielded by the new-found land. They did not exaggerate its value as they did that of the Sassafras and many other products of the American soil. There is no tree in America that will grow better fence-posts, for the wood does not decay and insects do not molest it. A well-selected Red Cedar post will last an incredibly long time in the ground; and for the sills of buildings placed immediately on the soil no wood is more valuable. Moths flee from its pleasant pungent odor, and every good housekeeper knows the value of a red cedar chest, or a closet lined with this wood. Red cedar is the wood of lead pencils; and practically the wood in all these indispensable articles, at least in pencils of good quality, is the wood of this tree from Florida, where there are great factories belonging to German manufacturers, devoted to cutting up cedar wood into pencil stock. Every artist in all the civilized world, every man of letters, every school-teacher, all the bankers, lawyers and other men of affairs, the men and women who control the world, and all the school-children who are going to control it, hold every day in their hands a piece of this wood. It would be interesting to know what proportion of these men and women, the most intelligent and best-educated of the human race, knows anything of the origin of these little cylinders of wood, of the character and appearance and of the name even of the tree that builds them up in its long life of slow accretions.

It is not our purpose to speak now of the botanical peculiarities of the Red Cedar, the *Juniperus Virginiana* of botanists, because they are perfectly well known to every one who is interested in trees in their scientific aspects, but of its horticultural or decorative value as an ornamental plant, because it does not seem to be fully appreciated or recognized in American plantations, at least in the eastern states, although in the west a few years ago it was largely grown by nurserymen and planted in considerable numbers on the plains and prairies of the Missouri River basin. In all the northern states the Red Cedar can be made to take the place in formal gardens of the Cypress, to which the gardens of southern Europe owe so much of their charm, and which cannot be grown in our severer climate. If it is desired to produce certain effects in a garden by the use of trees that are formal in outline, the Red Cedar will produce this effect better than any other tree that is hardy here; and if trees cut into fantastic shapes such as delight the Chinese or the Japanese, from whom the Dutch learned this fashion, no tree bears with less injury than the Red Cedar the annual suppression of its growth under the gardener's shears. In natural gardens also the Red Cedar can be made to play a useful, and sometimes an important, part, as no tree is better suited to enliven a broken, rocky hillside or to crown its top with its dark green foliage, which in autumn is studded with bright blue berries. Other coniferous trees with pyramidal habit, like the Arbor-vita, are often planted in such situations; but the Arbor-vita is a gregarious tree and an inhabitant of

swamps and low river-banks, and when it is made to stand out alone on a hill it never looks at home or in harmony with its surroundings, while the Red Cedar, of all our trees, most easily fits into its place in the landscape, and, perhaps, no one ever saw a Red Cedar that looked out of place in connection with its associates in any American sylvan landscape. As a hedge-plant the Red Cedar has not proved very successful; the plants grow too slowly for the impatient American, who wants his hedge to grow as rapidly as a carpenter could build one with boards, and the branches often die out, making here and there ugly gaps.

Like most other trees, the Red Cedar is easy to raise from seeds when the person who undertakes to do it understands its peculiarities. The stone enclosed in the fleshy berry of the Juniper is very thick and hard, and it takes a long time to soften so that the seed can get out and begin to grow. Planted in the ground in the ordinary manner a Juniper-seed will sometimes lie for years without germinating, and the way to treat them is to soak the berries thoroughly in warm water as soon as they are ripe in the autumn, mix them with sand, bury the whole mass in the ground in some place where they will keep moist during the following summer, and then plant them either in the autumn, a year from the time they were gathered, or in the following spring. Treated in this way the seed will germinate in a few weeks after they are planted, and produce strong plants the first year, which will be six or eight inches high at the end of the second season, and ready to transplant. Nurserymen do not raise Red Cedars very often now, for there is no great demand for them. Young plants can be transplanted from old pastures, however, or from the sides of walls or fences, where the seeds dropped by birds germinate in great quantities, producing the long lines of Cedar-trees which are conspicuous and beautiful features of the landscape in the northern and middle states.

The Red Cedar is a long-lived and hardy tree, and if any man has a fancy to plant for posterity or to preserve his memory in a tree, there are few trees that he can plant with greater assurance of attaining the object of his ambition.

The illustration on page 65 of this issue, made from a photograph, for which we are indebted to Mr. Charles S. Bradford, Jr., represents a venerable Red Cedar-tree of a common form growing near Wawa Station, Delaware County, Pennsylvania.

Black Locust in the West.

SO far as I know, the only place west of the Mississippi where Black Locust, *Robinia Pseudacacia*, is indigenous, is in Arkansas, where there is a heavy rainfall. But the species will flourish under widely different conditions of moisture, and it succeeds quite as well, even in high land, as any other tree as far west as the one hundredth meridian. It will not endure excessive cold, however, and it is not advisable to plant it north of central Iowa and the Platte River, in Nebraska.

Black Locust has been extensively planted in the prairie portions of Missouri, and in Kansas it is a favorite tree, owing to the great variety of soils in which it succeeds, its ability to withstand drought, and the superior excellence of its wood for post timber, and for all uses requiring contact with the soil. It is the hardest and most durable broad-leaved timber that can be grown in this climate, and as fencing is an important problem in the west, there is economy in including a good post timber in the shelter belt plantation. Black Locust seedlings have been extensively distributed by the Kansas Commissioner of Forestry. At the State Forestry Station, Ogallah (longitude $99^{\circ} 40' W.$), this tree is grown in high prairie, and trees seven years planted are as healthy as any on the grounds. The annual rainfall at Ogallah is about twenty-four inches. At the Kansas Agricultural College, Manhattan, Black Locust and Catalpa have been used as nurse-trees for Oaks. The Locusts have not done especially well in this mixture, growing about as rapidly as the Catalpa. The Locust is a

light-demanding tree, and should be planted in mixture with good shade-enduring kinds, such as Russian Mulberry and Wild Cherry. The trees should be set close—not more than four feet apart both ways, and three feet is better. This close planting will force them tall, and as in post timber length of trunk is a most important consideration, the importance of plenty of shade-making trees and close planting will be recognized. The Locust should not constitute more than one-fourth of the plantation. Mixed planting will also tend to lessen the danger of damage from borers, which cause much injury to trees of this species.

Washington.

Charles A. Keffer.

California Experiment Stations.—II.

THE Forestry Station at Santa Monica, in southern California, occupies a most interesting and picturesque site. The town of Santa Monica is, perhaps, as well known as any part of the Californian seacoast, because it is particularly accessible from Los Angeles by railroad, and has become the leading watering-place between Coronado and Monterey. A long sweep of seashore, bold, high cliffs, with an almost level plain above them, rising north and north-east to the bluest of mountain ranges, and traversed by deep barrancas or straight-sided cañons, such is the general aspect of the great Santa Monica rancho. Fifty years ago a hundred thousand acres here, the estate of an old Spanish family, supported vast herds of horses and cattle. Then came the railroads—the American town-builders. Senator Jones, of Nevada, and others bought the ranch, founded the town, pushed out an immense wharf a couple of miles away, at Port Los Angeles, where the steamships land, and Santa Monica, upon the frostless bluff overlooking the blue Pacific, began to take shape. Now one sees there rows of tall Bananas, heavy-fruited, all winter long; Tacsonias and Passifloras grow and bloom, and semi-tropical gardens surround costly cottages on every hand.

The greatest and deepest barranca in this entire Santa Monica plain is that known as the Santa Monica Cañon. It is not really a cañon in the strict interpretation of the Spanish word, which refers to mountain ravines, but more nearly conforms to the Spanish idea of a barranca, a wide cleft across the plain from the mountains to the sea. In reality there are two large barrancas there, running in a direction somewhat parallel for four or five miles, although they are sometimes close together, and at other times wide apart. The narrow tongue of land between them extends to within an eighth of a mile of the ocean. The two streams of water that flow through these deep and well-wooded depressions unite at the foot of this gradually sloping tongue of land that overlooks the seabeaches. Here, on the sides and summit of this narrow central plateau, between two deep gorges, the Santa Monica Forestry Station is situated. It is almost completely hidden from the town and the watering-place. It is greatly sheltered from storms, and yet the view from its heights is wonderfully extensive.

To the tourist driving northward from Santa Monica, along the cliff overlooking the Pacific, the dry level plain seems to stretch unbroken, except by slight depressions, for twenty miles. Suddenly, by an old adobe ruin, he pauses, at the verge of a cliff; a hundred and fifty feet below, the Santa Monica ripples over its pebbles and through its groves of giant Sycamores, which rank among the noblest in southern California. Half a mile beyond, the plain continues again on the same level; between the two divided fragments a narrow tongue of rocky land projects and sweeps in long curves downward to the Sycamore groves. Eastward, along the ascending lines of the vast chasm, are darker and larger masses of forest, Walnut, Oaks, Cottonwood and other groves of Sycamores. Beyond, and at points of vantage on the sides of the descent, are plantations and avenues of various species of Eucalyptus. The cultivated fields cease at the edge of the gorge, and only begin again beyond the further cliff; the space be-

tween, painfully cleared in spots, and planted with grass and corn, is for the most part wild land thickly overgrown with lesser forms of vegetation, except where richer soil or the nearness of water has enabled native trees to gain a foothold.

The twenty acres belonging to the forestry station, a little arboretum tract, with hardly any waste upon it, extend from the bottom of the northern Santa Monica cañon, up slopes and across levels to the very top of the mesa, on the same plane as the town itself, and look down from thence to the bottom of the south cañon. Three distinct levels and two half-levels, with their connecting slopes, not too abrupt for planting—such is the charming topography of the station lands. Given five acres more of rough, stony western frontage sloping to the sea, and ten acres toward the east to carry the boundaries to natural lines, and the forestry station need ask nothing else in the way of land endowment.

The soil is rich and varied, suitable for good tree-growth and easy to till. Frosts, noticeable on the lower part of the tract, lessen as one ascends. Climatic observations are being kept on each of the three principal levels of the station.

According to the reports of the late State Forestry Board, the Santa Monica Station was founded December 20th, 1887. At that time Mr. Abbot Kinney was chairman of the Forestry Board, and I think it probable that he was mainly instrumental in the choice of the beautiful tract now occupied by the station. A fine collection of some forty species of Eucalyptus and Acacia was planted near the foreman's cottage, and these are now beginning to make a fine show. This collection, and also many choice single trees and some avenue work, were done during Commission days. The University has added to the collection, has cleared a good deal of brush-land, has greatly developed the water-supply, and is establishing a choice nursery of rare trees. All this takes time, and it may be several years before the scientific results of observations upon tree-growth here afford much data for publication.

Mere lists of species planted are seldom valuable. The phenomenal range of soil and climate offered to the forester here can best be shown by a few memoranda :

On the lowest and coldest level, three or four feet above the creek-bed, are Camphor-trees, several Hakeas, a Banana, Dracenas, an immense mass of the Hawaiian Taro, *Caladium esculentum*, growing in the moist soil that receives the overflow from a hydraulic ram used to lift water to the dwelling-house, a hundred feet higher. Tender species of Eucalyptus and other trees are grown in seed-beds here. The soil is a light sandy loam, mixed with leaf-mold from the Willows, Cottonwoods and Sycamores that shelter and half surround the place.

The bluff between the lowest level and the main or cottage plateau is heavily wooded except where nearly perpendicular. It is moist, with springs and green with vines and beautiful undergrowth. Here Azaleas, Rhododendrons, Camellias, Kalmias, Magnolias, Clematis and similar species are being planted by the roadside or in the small clearings in the rich loam at the base of the bluff. Broom and Gorse are being naturalized higher up the bank. One more sunny place, a hollow of rich, black peaty soil, has been occupied by a score of Fig-trees of different varieties and by clumps of Bamboos. Olives, too, have been planted—fifty trees in eleven varieties. It serves to illustrate the range of possibilities here, that on a wind-exposed point, not a hundred feet from where the Figs and Olives are thriving, a mass of close-set *Pinus Austriaca* has proved itself at home.

The middle plateau, where the Eucalypti and Acacias are chiefly planted, also contains the beginnings of a Palm collection, a *Jacaranda mimosifolia* (one of the Rosewood-trees), and a large number of tender trees and shrubs. The soil is a loose, rocky loam, warm, light, and needing no irrigation for trees set early in the season. The growth of *Quercus Cerris* and *Q. Robur* have been most satisfac-

tory. The scarlet Hibiscus and the scarlet Passiflora, *P. incarnata*, have not shown a sign of injury in winter. The native growths are *Quercus agrifolia*, *Rhamnus Purshiana*, *Juglans Californica*, and large Elders, some of them thirty-five feet high, with trunks eighteen inches in diameter.

The second steep bluff, another hundred feet high, that lies between the middle plateau and the mesa, contains enough soil for trees and shrubs, and is being cleared preparatory to planting. This portion, as well as the top, requires great care to secure a tree-covering. It may be considered as fairly representative of an immense area of mesa-lands in California. The native growth is *Rhus laurina*, *Rhamnus Purshiana*, the so-called wild Coffeeberry of California, with *Paeonia Brownii*, *Salvia spathacea*, and the inevitable host of *Compositae*. In spring-time the mesa is very beautiful.

Several rows of large *Eucalypti* border this upland; the middle portion of seven or eight acres is unplanted, except for some Ashes and Olives, which have done very well, and here, rather than on the lower plateaus, the first scientific effort at establishing a mixed high forest will probably be undertaken as soon as the soil is in good condition and the trees ready. The Cork Oak, *Quercus Suber*, has done so well in southern California, surpassing in rapidity of growth any other Oak, and Oaks are so well indicated by the native growth of the plateau that a grove of Cork Oaks will probably be placed there. But the more valuable species of *Eucalyptus* and *Acacia* seem to be more nearly adapted to the mesa.

The chief value of a forestry station on so small a tract must be on its arboretum side, and, fortunately, this station is so near Santa Monica and Los Angeles that a summer school of forestry, with popular lectures, would be well attended. Its importance as an educational centre in years to come cannot easily be estimated. If the National Government creates an adequate forestry system for maintaining and managing the present reservations in California and elsewhere, a place like the Santa Monica Station might in time offer many advantages for a school of forest-science.

Niles, Calif.

Charles Howard Shinn.

New or Little-known Plants.

New Cypripediums.

CYPRIPELUM SALLIERI PICTUM.—This is a cross between a fine variety of *Cypripedium insigne* as the seed parent and *C. villosum albo-marginatum* as the pollen parent. The dorsal sepal is large and slightly reflexed at the base; the lower half is greenish yellow, heavily marked and lined with purplish brown, which on entering the pure white upper half becomes rich violet. The petals and pouch much resemble those of *C. villosum*. Only two plants of this fine variety are known in cultivation, one of them having its home in the well-known collection of Hicks Arnold, Esq., of New York.

CYPRIPELUM NITENS PITCHERÆ.—This variety of *Cypripedium nitens* is the result of a cross between *C. villosum* as the seed parent and a very fine variety of *C. insigne* as the pollen parent. The dorsal sepal is very large and broad, with a deep white margin. The centre part is light green, heavily marked with large spots of dark brown, some of them measuring from three-eighths to half an inch in length, and extending into the white margin, where they become violet in color. The petals and pouch resemble those of *C. villosum*, but are much finer in form and deeper in color. The crossing was done December 24th, 1891; the seed was sown June 19th, 1892, and the plant flowered January 23d, 1895.

CYPRIPELUM CALYPSO ROTHWELLIANUM.—This is a noteworthy hybrid, having for its parents *Cypripedium Boxallii superbum* as the seed parent and *C. Spicarianum roseum* as the pollen parent. The leaves are broad, about seven to nine inches in length, of a dark green color. The dorsal sepal has

a very heavy midvein of deep purple from base to apex, and the whole sepal is densely suffused with the same color, with the exception of a narrow white margin. The petals are slightly undulated, of a brownish purple color, with a heavy midvein of dark purple. The pouch is the same color as the petals, and the staminode is pale lilac, with a green spur in the centre. The plant was raised by Pitcher & Manda, at Short Hills, New Jersey, and named in honor of J. E. Rothwell, Esq., of Brookline, Massachusetts. The seed was sown January, 1892, and the plant first flowered in January, 1895.

CYPRIPEDIUM JANUS.—This is a distinct and beautiful hybrid between *Cypripedium villosum superbum* as the seed parent and *C. Leeannum Masereelianum* as the pollen parent. The leaves resemble those of *C. Leeannum*, only they are more erect in habit; they are from six to eight inches long and one and a half inches broad. The dorsal sepal is large and flat, with a broad white margin prolonged to the base; the centre part is delicate green, nerved with a darker shade of the same color, and heavily marked and spotted with blackish brown. The inferior sepal is pale green, veined with darker green. The petals are broad, with a heavy purplish brown midvein, the upper half brownish purple on a green background spotted with purple; the lower half is lighter in color and more densely spotted. The pouch is shiny, yellowish green, tinted with purple, veined and lined with dark green. The staminode is purplish green, having a bright green spur in the centre. The parent flower was fertilized October 23d, 1891; the seed was sown March 18th, 1892, and the plant flowered January 24th, 1895.

Plant Notes.

SEMELE (RUSCUS) ANDROGYNA.—This plant is a native of the Canary Islands, and, although long in cultivation, is rare with us. There are a few plants in the neighborhood of Boston, which were undoubtedly brought from Fayal, where it is, of course, hardy, and is frequently planted. It is a greenhouse evergreen climbing shrub, closely related to *Asparagus*, and might be described as a huge *Smilax*, namely, *Myrsiphyllum*, entirely lacking the grace of its relative, but more than making amends for this deficiency by its bold and vigorous growth. At this season of the year, or a little earlier, stout stalks, resembling a large and much elongated *Asparagus* head, are thrown up, and, under favorable conditions, attain lengths of twenty feet or more; from these spring numerous branches which look like great pinnate leaves. The true leaves, however, are almost unnoticeable scales at the base of these apparent leaves or cladodes. Early in February the small white flowers are produced in large numbers on the margins of these false leaves, giving the plant a very singular, almost unique, appearance. The flowers are succeeded by round pulpy berries, not common with us. This *Semele* should be planted out in a well-prepared border of rich soil, in a cool greenhouse, and trained over a back wall or on the rafters; it is too rampant a grower to succeed in pots or tubs, unless they are very capacious. A well-established plant will furnish quantities of foliage admirably adapted to household decoration, particularly where bold effects are desired. The propagation is by seeds, which sometimes require two seasons for germination, and are not always easily obtainable, or by division, which is a slow and unsatisfactory method; these difficulties probably account for the scarcity of the plant in cultivation.

DANAË (RUSCUS) RACEMOSA.—This plant is not unlike *Semele*; indeed, they have both been known by the common name of Alexandrian Laurel, but the *Danaë* is less exuberant in its habits of growth. It has branching stems, and its general effect is more graceful, reminding one of some of the Bamboos. It grows three feet or more in height, and makes a good pot-plant; it can also be satisfactorily grown in a greenhouse border. The cladodes are lanceolate, an inch and a half or two inches long, of good vivid green, and well fitted for any decorative use which

requires lasting foliage. The flowers are small, borne on the end of the branches, and are followed by bright red berries, which are occasionally produced here in limited quantities. The propagation is the same as in *Semele*. A recent article in *Revue Horticole*, No. 23, 1894, p. 545, gives a description of these two plants, and also of several species of *Ruscus*; none of the *Ruscus*, however, are desirable for ornamental purposes; they are simply curious and of botanical interest only.

CENTROPOGON LUCYANUS.—Mr. Cameron writes that this beautiful plant has been for some time flowering in a moderately warm greenhouse at the Harvard Botanical Garden. It was raised about thirty-nine years ago by Monsieur Desponds, of Marseilles, being a hybrid between *Centropogon fastuosus*, another good plant, and the Brazilian *Sipho campylos betulæfolius*. The plant has a half-procumbent habit, and the stems are clothed with oblong, lanceolate leaves. The tubular, rosy carmine flowers are borne at the ends of the branches. As a winter-flowering plant for the warm greenhouse this *Centropogon* has much to commend it. Its blossoms are not only showy, but a succession is kept up for a long time. The plants can be raised annually from cuttings taken in the spring. If the cuttings are placed in sand with a good bottom-heat they hardly ever fail to root. When rooted they should be put into small pots of light rich soil and shifted on as required during the summer. In spring the young plants need a rather warm greenhouse, but in summer a cool, moist, shady house or frame suits them well. Perhaps, in no better way are the flowers of this plant shown to advantage than when the plants are grown in baskets suspended from the roof. The drooping habit of the plant suits it admirably for this treatment.

GYNURA AURANTIACA.—This composite plant was introduced from Java about fifteen years ago. In a warm greenhouse this is its flowering season, but the plant is not grown so much for its flowers as for its beautiful foliage. It grows from two to three feet high, and its stems are well clothed with leaves from four to six inches long and three to four across, and these are furnished over their entire surface with small hairs of a beautiful violet color. The small flower-heads are produced in corymbs and are of a brilliant orange color. It is propagated by cuttings, which root easily, and the plant enjoys a light open soil and a warm greenhouse. With its beautiful stem and leaves it makes a plant which is useful whenever handsome foliage is wanted.

THUNBERGIA ERECTA.—This west African plant is, perhaps, better known in gardens as *Meyenia*. It is almost a constant bloomer, but flowers most profusely during the winter months, and at this time it is one of our prettiest of dwarf stove-shrubs. It is a much-branched plant, and when not pruned too hard has a graceful habit. The small, dark green, ovate leaves are set thickly on the branches, and even when the plants are not in flower they make handsome small bushes. The dark blue flowers are produced singly in the axils of the leaves, and are about one inch and a half long and about the same across. Young plants are obtained from cuttings of the young wood, which root easily at any time. The variety with white flowers is also in bloom now, and makes a good companion plant to the blue-flowered one. This *Thunbergia* and its variety thrives in a stove, where it will get a strong moist heat, and in a rich open compost.

Cultural Department.

Vegetables under Glass.

FORCING BEANS.—No beans are better for forcing than the group known in European gardens as French, or Dwarf Kidney Beans. In this country we call them String Beans, but the term is very vague, and applies, apparently, to all beans whose pods are used for kitchen purposes. Several varieties of the Bush Lima and French sections have been in active growth here for some weeks past. Two varieties of the Bush

Lima, Henderson's and Burpee's, were sown in the same bench on January 2d. Under summer outdoor cultivation the Bush Limas are bushy in growth and seldom more than eighteen inches or two feet high. In the greenhouse, however, Burpee's Lima has become a true runner, and with few lateral shoots the main stems are already six feet in height, and are now developing a few flower-clusters toward the top. Plants

benches, and for some reasons pot-culture is to be preferred. The plants in pots were sown December 5th, and we have been picking marketable pods from them since January 25th. The bench plants are just coming into bloom, and even with the increase of light and sunshine three weeks will probably elapse before they will be ready to pick. In the matter of earliness the plants in pots clearly have the advantage. The

Fig. 9.—A Red Cedar in Eastern Pennsylvania.—See page 61.

of Henderson's, on the other hand, although sown at the same time, are only twelve inches high, and are showing some inclination to run, with no indication of flowers or branches. I am unable to account for this difference in these two varieties, and their change in habit of growth is likewise puzzling.

With the French, or Dwarf Kidney Beans, we have been more successful. These have been grown in pots and on

pots are convenient since they can be used to fill small vacant spaces which occur in most greenhouses from time to time, such as otherwise might go to loss. We use any ordinary potting soil that may be handy, loam largely predominating, and seven-inch or eight-inch pots, and sow about a dozen seeds in each pot. Later on the plants may be thinned out to half that number; but, as seedling Beans in greenhouses are

subject to damping-off fungi, it is advisable to sow a few extra seeds in each pot. A high temperature, not lower than sixty-five at night, is the best, and where the plants are grown for more than one gathering of the fruits, they should be watered occasionally with weak liquid-manure after the first picking has been made.

In cultivating Beans on benches we sow the seeds in lines about eighteen inches apart, afterward thinning out the plants to two or three inches apart in the rows. The damping-off fungi and red spider are the most destructive enemies of these plants under glass. Moist soil and atmosphere encourage the growth of the fungi, and the same conditions keep the red spider in check. We have found, however, that sulphur or powdered charcoal, scattered among the plants, will retard the injurious effects of the fungi, and a diluted kerosene emulsion, applied frequently, destroys the red spider.

We have grown three varieties of these French Beans—Emperor William, Early Warwick and Syon House. Early Warwick is a very good sort, producing a good crop, somewhat in advance of the others. The growth of Emperor William is weakly, and the crop poor; but Syon House is, by far, the best of all for general purposes; it is strong and healthy, and produces a large crop of excellent pods.

TOMATO IGNOTUM.—This excellent variety is an admirable copper out-of-doors, and is, perhaps, the best Tomato for forcing. The fruits are of good size, smooth and handsome in appearance and of excellent flavor. Large tomatoes are liable to crack, and whatever other good qualities a tomato may have it is comparatively worthless if it cracks. The Ignotum never cracks, and yet the skin is neither so thick nor so tough as is that of many tomatoes that do crack. We have one house almost exclusively devoted to this Tomato, and the crop has been uniformly excellent. The plants are mostly grown to a single stem, and one such plant has already produced two pounds of first-class fruit, with good promise of three pounds additional. It may be added that a single fruit on this plant weighed eight and a half ounces. The Ignotum was a chance seedling from a small German variety found on the grounds of the Michigan Agricultural College by Professor L. H. Bailey some five or six years ago. It has been offered by the seedsmen each year since 1890.

M. Barker.

Cornell University.

Violets.

If there was as much certainty of success with Neapolitan Violets as with many other florists' flowers, they would be abundant and cheap, but the difficulties attending their cultivation will always make them highly prized flowers. They simply need a good soil, with some proportion of lime in its composition, and sunshine and all the air possible during winter-time. A comparatively low night temperature of thirty-five to forty degrees, Fahrenheit, will give a long season of bloom with large flowers, though not many at a time. With a temperature of forty-five to fifty degrees the flowering season will be shorter, with an enormous crop during January and February. If we may consider the normal temperature of these plants to range from forty degrees down to almost freezing-point, it follows that they are forced to a certain extent whenever they are grown in a temperature above forty degrees. Violets in frames are frequently subjected to a few degrees of frost, and when kept screened from the sun's rays until they are thawed out the plants do not suffer. Some of our best growers use frames altogether, and, except for the misfortune of disease, have been generally successful, especially with Marie Louise.

Damping in frames has always been a source of trouble. This is a kind of black mildew, which quickly spreads if the plants are not carefully looked over every day or two. The largest and healthiest plants are almost always the first to be attacked. It is difficult in winter, especially with frames, to air sufficiently, and the disease spreads quickly if the frames are closed for a day or two, as often happens during a period of bad weather. A dry atmosphere seems essential. Some growers use a mulching of dry horse-litter, well rotted, composed mostly of droppings. This, it is claimed, takes up the surplus moisture given off during the night and when the frames are closed, liberating the moisture when the frames are opened. No doubt, this would act beneficially in reducing the danger of damping, if air could be given every day. Other growers use dry sand with the same object. If it does no more, it makes a clean cover for the ground and keeps the flowers from soiling. This practice we follow here, and I have noticed that the sand is moist in the morning, and quickly becomes dry during the day when air is given. When the Violets have been poor I have tried everything that promised

to be of benefit to them; among other things, powdered charcoal and sulphur. I still think this was effectual against disease, but objectionable on account of the odor.

The Marie Louise is the most popular of all the Neapolitan Violets. It is, however, the most difficult one to grow, and Lady Hume Campbell is now very largely grown in its stead. The color of the latter is blue rather than violet, and mauve would be, perhaps, the most correct designation. The popularity of the violet shade seems to be all a matter of taste, and unexplainable in any other way. The tone of the Lady Hume Campbell is decided enough.

A gardening acquaintance of mine is having wonderful success with Marie Louise grown in pots in the greenhouse in a night temperature of about fifty degrees, but for one grower who succeeds on this line a dozen fail. To chronicle the various methods of different cultivators who have succeeded would take up much space. Some grow in pots, others in frames; some in light soil, and others in heavy; some in shade, and others in sunshine; some in a greenhouse with Carnations, at a night temperature of fifty degrees, and others in a temperature very little above freezing. The successful plan of one year too often fails the next. I have tried about every way I could think of. I have potted rooted runners from the bed in February, thoroughly hardened them off, and planted them in May in specially prepared soil, with lime and soot worked in. The result was a splendid growth until August, when the spot attacked them. The sight, and smell for that matter, of these diseased plants was so distressing that I have taken another path rather than pass by them. I started the next season with fresh stock which never had been diseased. I was informed that a successful grower divided his plants, so I tried this plan, but succeeded no better; I think dividing the old stools the worst plan of any, for if any disease lurks on the foliage or the roots it is apt to be perpetuated in this way. This is especially the case with the nematodes, sometimes called club-root. It is said to be the work of a small worm, which makes a gall on the root about the size of a grain of mustard-seed. The work of the nematodes is so insidious in its character that plants will thrive, appearing healthy and even vigorous. But the plants, when taken up in the autumn and put into frames, scarcely ever bloom, and gradually dwindle away. Curling, scorching leaves are a sure indication that the pest is at work. According to those who have made a special study of this pest, some of its species are common in most gardens, especially such as have been under cultivation a long time. I find it on Begonias, Salvias, Asters, Heliotrope, Abutilons, Roses, Lettuce, Cucumbers, Melons and Tomatoes, and I have also found it on many weeds. It appears that to avoid this disease we should select a piece of new ground. Information as to how to prepare ground so that it would be free from germs would be valuable. Rotation of crops might work to this end, if we only knew which are pest-proof. In preparing soil for Violets last season I adopted the plan followed by Mr. Montgomery, of the Waban Rose Conservatories, of heating the compost with fermenting materials, bone-meal being the principal agent. The temperature thus attained is such that all insect life is destroyed.

When I imported Lady Hume Campbell, four years ago, it was so badly infested with nematodes that I had some difficulty in saving it. The flowers were poor in size and color, compared with those now in bloom. Gradually, however, by taking cuttings instead of runners, as I had formerly done, I brought them into a healthy condition. This season they are very fine, and average 1,000 blooms a week on 208 plants, last week giving 1,200 flowers.

Last June I thoroughly cleared the bench and lime-washed it, and being sure that the compost was free and the stock healthy, I planted on the 10th of that month. The sashes are removable, and the plants remained exposed to the full sun during the whole summer. I gave them an abundance of water when well established, but no stimulants. They made splendid growth, and never showed any trace of disease. Some stock which was left over from the year before was planted with a doubtful lot of Marie Louise in the vegetable garden, and showed disease. As a preventive I used two gallons of prepared Bordeaux mixture during the most dangerous months, August and September. Whether I owe anything to its use I do not know, but this I can say, that on the diseased plants in the garden those sprayed were as badly diseased at the end of the season as some few plants which were left unsprayed, for experiment. My conclusions on the application of copper compounds are that they may be excellent preventives, but of no use where the disease has got headway. It ought to be generally understood that it is not claimed that the copper compounds are curative, but only preventive—that is, they will not kill the fungus which is at

work within the plants, but when healthy plants are covered over with a thin coating of the mixture the spores of the fungi will not germinate and infect the plants.

The Messrs. Farquhar, of Boston, state that their new Violet is a sport from the Lady Hume Campbell. If so, it is an acquisition. I have examined it, and, so far as I have seen, it is healthy. The flowers are much larger than those of the Marie Louise, and of identically the same shade.

Chrysanthemums.

THE propagation of Chrysanthemums must begin at once if good strong plants are desired. The first essential is the selection of good cuttings, and this does not mean large soft shoots, which are harder to strike, and after they are struck throw up a soft weak growth, from which good blooms cannot be obtained. A firm, short-jointed cutting, although smaller at first, will in every case make the best plant in the end. Another mistake is to strike the cuttings in too much heat, and in this way a great proportion of Chrysanthemums are ruined at the very outset. A temperature of forty to forty-five degrees at night is quite high enough. The cuttings may be struck in a propagating-bed in sand, in boxes, or singly in pots, in a light sandy mixture. The pot method, where space can be spared, is, no doubt, the best, as the plants receive less check in shifting, and this should be avoided in the first and in the successive shifts. The main point in Chrysanthemum-culture is to keep the plants growing continuously, and they should never be allowed to be checked through any cause; they should have free exposure to light and air and the general conditions which will induce free, but firm, growth.

Tarrytown, N. Y.

William Scott.

Winter-flowering Begonias.—Young plants of these Begonias, from spring-struck cuttings, have with us proved better than old plants, as they flower more freely and throw better blooms. The cuttings are struck in February, and kept growing freely under glass until August, when they are removed to a cold frame. The pots are plunged in ashes or leaves and gradually exposed to air and sunshine. Finally they should be left uncovered by night and day, so as thoroughly to ripen the wood. They should be moved inside before danger of frost. They bloom profusely all winter through in a light airy house with a temperature of fifty-five degrees at night, allowing a rise of fifteen degrees by sun-heat.

Correspondence.

The Saghalin Knot-weed.

To the Editor of GARDEN AND FOREST :

Sir,—Wide publicity has evidently been given to the short note I published in GARDEN AND FOREST of October 11th, 1893, on *Polygonum Sachalinense*. These observations were simply as to its remarkable growth for a period of twelve years here at the college under all conditions. It spreads so freely by its underground stems that it may be an extremely pernicious weed, as some other members of the genus *Polygonum* are in the west, notably *P. Muhlenbergii*. Land set aside for "Sacaline" may have to be given up forever to it, just as in the case of Johnson Grass in the south.

As to its feeding qualities there may be question; as yet no one in this country has tested it, and I understand there are some unfavorable reports from Europe. Corn will still continue to be the best forage-plant in the Mississippi valley. I do not believe that any plant, whether used for ornamental purposes or in horticulture or agriculture, should be recommended for general or extensive use until it is sufficiently tried under all conditions, climate and adaptability to soil.

Agricultural College, Ames, Iowa.

L. H. Pammel.

[We observe that GARDEN AND FOREST has been referred to in several circulars as having advocated the use of this Knot-weed as a forage-plant. Two years ago, when the eminent French horticulturist, Monsieur Charles Baltet, reported the enormous growth of this plant, our London correspondent referred to it as a matter of news, and we afterward stated that a near relative of this *Polygonum*, *P. cuspidatum*, a plant which had also been commended for its economic value by some European authorities, had proved an aggressive weed in Central Park. However, we suggested that it would be worth while to try these *Polygonums* where no other forage-plant will grow,

although it was added that we did not think it probable that they would ever supersede Indian Corn in the Corn belt of this country. It is wise to test any plant which comes well recommended, but we agree with Professor Pammel that it is not safe to be confident about the value of any novelty until it has been thoroughly tested.—ED.]

New Orchid Baskets and Plant Tubs.

To the Editor of GARDEN AND FOREST :

Sir,—When visiting the greenhouses of Mr. Adolph Schoeninger, of Chicago, some time ago, I was impressed with the neat appearance of his collection of Orchids. There were no unsightly baskets or ugly pieces of half-rotten or charred wood, which too often annoy the eye in such places. Most of these Orchids are grown in neat baskets suspended from the roof or on benches, in cylinders and on flats of different sizes and design. Not being satisfied with the square baskets so commonly in use, Mr. Schoeninger constructed for his collection different styles of baskets and rafts, using at first cedar, pitch-pine, maple, cherry and other woods, but at last decided upon the wood of the southern Cypress, which is almost as durable as red cedar and much cheaper. For such plants as are usually grown on pieces of wood or cork, rafts were constructed, made of octagonal strips of cypress wood, pierced with holes through which runs a copper or galvanized wire. The strips are kept apart by turned buttons of the same wood. The Orchids on these rafts are growing in sphagnum moss and Fern-roots, and are fastened to the bars of the rafts by wire. Epidendrums, several Dendrobiums, Stag-horn Ferns and a number of Bromeliads are grown on these flats. Through the pliability of the wire the sides of the rafts can be turned up so that they assume a boat-like form. Filled with crocks, charcoal, peat, Fern-roots and sphagnum moss, they serve, in this way, the same purpose as the common baskets. In these boat-shaped appliances many Orchids, Tillandsias, Pitcairneas, Billbergias, Caraguatas, several species of *Æschynanthus* and Peperomia can be grown successfully in a warm, moist house. Larger flats can be turned into cylinders, and in this way they are excellent receptacles for Vandas, *Ærides*, Angræcums, etc.

Most of the Cattleyas, the large-growing Dendrobiums and many Lælias, however, are grown in 'pot-like' baskets, which are also constructed of cypress wood in sizes from four to twelve inches across. The roots find an excellent hold on the numerous bars on whch they run up and down in tangled masses. Besides their neat appearance, the peculiar shape of these baskets induces the plants to root freely, giving them an advantage over the baskets in which Orchids are generally grown. Another advantage of these baskets is that they can stand on the benches like flower-pots, or they may be suspended from the roof like other baskets. They have movable bottoms, which are firm when in position.

Mr. Schoeninger, who is an enthusiastic amateur gardener, spends much of his leisure time in his greenhouses, trying to grow his plants into healthy specimens. Being dissatisfied with the clumsy appearance of the common tubs where Palms and other large-growing plants are usually grown, Mr. Schoeninger invented a new, neat and simple flower tub, which has also the advantage of being very durable. Instead of the common hoop, a strong copper or galvanized wired is used, which runs in a groove around the staves. The ends of the wire are fastened neatly under the handle by the turning of a nut. The handle is so constructed that the small tub can be lifted by hand; in case of larger ones, sticks can be placed under the handle, thereby allowing any weight to be lifted with ease. Cast-iron feet are attached to keep the tub from the floor, allowing also a free circulation of the air and a good drainage. There is a neatness about these tubs and baskets not found in any other I am acquainted with. They are also exceedingly cheap.

Meetings of Societies.

Nebraska State Horticultural Society.—III.

OUR report of the successful annual meeting of this society concludes with abstracts of two papers on Grape Growing:

THE MANAGEMENT OF VINEYARDS.

A paper by Professor F. W. Card on this subject began with suggestions on the selection of a site, which he said was more important than that of soil. Any open or well-drained soil will

answer, but the familiar phrase, "vine-clad hills," indicates that high lands have been recognized always as the natural home of the vine. This is because such situations are warm and dry, and in our climate they are less subject to late spring frosts, owing to the fact that they have what may be called good atmospheric drainage. Cold air settles into the lowest places, and the high knoll may often be above a cold stratum of frosty air in the valley below.

Analysis of the grape made in California shows that a crop of three tons of grapes to the acre takes from the soil thirty pounds of potash, a little more than nine pounds of phosphoric acid and a little more than ten pounds of nitrogen. This shows that about three times as much potash is used as either of the other ingredients. The ingredients of stable-manure are out of proportion to the needs of the grape, and it should generally be supplemented with potash of some kind. Stable-manure should be used with caution on thin land, and applied late in the fall or early in the winter, so that it will be available for early spring use. When applied in the spring there is danger that it will induce a late autumn growth and render the vine liable to injury in winter. An essential preliminary in the preparation of the ground is deep and thorough cultivation, and it seems to be the experience in most grape-growing regions that deep planting is better than shallow planting. Ten inches is generally recommended as the proper depth for planting throughout the grape-growing regions of western New York, and some growers advise as deep as twenty inches even in heavy soils.

In most cases the question of fertilizing the blossom is not an important consideration in planting, but such varieties as Brighton and Rogers' Hybrids must be planted near other sorts which will pollenate them. Some growers advocate that future efforts in the production of new varieties should be in the line of separating the sexes, as has been done in many of the Strawberries. It is said that the production of two crops, one of pollen and another of fruit, is too severe a tax on the energies of the vines. Besides this, pollen grown from male plants is said to be larger in grain and more potent than those from perfect flowers. Whether this division of labor should be encouraged may be questioned, but the character of the individual varieties in this respect is worthy of attention always, and especially in estimating the merits of a new sort.

After the vines begin to bear, of course, cultivation should never be neglected, especially in dry seasons. It is an advantage to have the soil covered with some growing crop in winter if this can practicably be done. The best crop for this purpose is one which will start late—not earlier than the middle of August—and make a rapid growth before cold weather, so that it will form a good covering for the winter. Wherever the winters are sufficiently mild, Crimson Clover seems to give the best satisfaction for this purpose, and in the west and north-west, perhaps, the common Field Pea approaches nearer the requirements than any other plant. Crops which can be put into the vineyard early in the season would rob the soil of much of the moisture which needs to be so carefully husbanded for the grapes, but if the vineyard has been thoroughly tilled during the early part of the year the injury from the late crop will be slight, and by the time the green crop will make any serious draft on the moisture of the soil the fruit is off and the vine should have ripened its wood for the winter. Professor Card's address concludes with an elaborate description of the various methods of pruning and training.

THE RELATION OF CLIMATE TO GRAPE-GROWING.

An interesting paper on this subject was presented by Professor G. D. Swezey. Last year he was able to trace a close relation between the amount of rainfall during the growing season and the yield of the apple-crop. He was not able to trace such a relation between the rainfall and the grape-crop, however. Indeed, a wet May is unfavorable to the grape-crop, by giving better conditions for the growth and propagation of fungi. Severe winters have, in some cases, caused the destruction of the crop even when the vines have been laid down and covered. Spring frosts, however, are the worst climatic enemy of the Grape. The conditions favoring a frost are the absence of wind and clouds and the continuance of a low temperature for some hours. Nearly all the temperature observations at the United States Weather Stations are taken on the top of buildings at a considerable distance from the ground. At the station at Lincoln the thermometers are seventy-five feet above ground. For a period of thirty days during the last of October and the first of November, comparisons were made between the temperature at this point and at the ground. Once during that time there was a difference of twelve degrees

between the minimum temperature on the roof and at the ground. A difference of six or more degrees was found on seven out of the thirty mornings. One of the chief effects of wind is in mixing the upper and lower layers of the atmosphere which prevents this excessive cooling of the lower layers. A moist atmosphere is one of the conditions which tend to prevent the occurrence of frost. The moister the atmosphere the higher the dew-point, and if the dew-point is above thirty-two degrees, so that dew begins to be deposited before frost comes, this is likely to prevent its occurrence altogether, for in the change from vapor to dew heat is constantly given off. This is one of the reasons why frosts are more common in the dry interior climates than in the moister eastern ones. The building of fires in the vicinity of the vineyard when frost is imminent is of value in two ways: by forming a cloud of smoke and thus preventing radiation, and by stirring up the atmosphere by the formation of upward currents of air.

Western New York Horticultural Society.—III.

THE following is a continuation of the proceedings of the late meeting of this society at Rochester:

NOTES ON ADULTERATIONS.

Dr. L. L. Van Slyke, of the Geneva Experiment Station, gave some instructive notes on the ways in which chemical adulterations affect the interests of fruit-growers. He spoke of the use of tin containing considerable quantities of lead, and thought influence should be brought to bear to have canners use only the better quality of tin, especially with the more acid fruits and vegetables, such as tomatoes, because of the danger of dissolving the lead. This also applied to the solder, as the more lead there was the more easily it melted, and hence solder containing much lead was often used. He drew attention to the higher color of French peas, due to coloring by copper. He also spoke of salicylic acid used for preserving fruits, which, though not a poison, is an irritant to the stomach. In unfermented wines alcohol is often added to preserve them, and vinegar is diluted with sulphuric acid and water. In the case of jams and jellies a cheaper material is often mixed with a more expensive one, and the whole sold under the name of the more expensive. For jams refuse material is often used, and many fruit jellies are made without any fruit, even for the flavoring. Among many samples examined, one of quince jelly was composed largely of beet-sugar and glucose, with flavoring composed of acids. Of thirty-two jellies and jams examined, twenty-nine were adulterated. A large number of the fruit essences are adulterated, especially pineapple.

In discussing the relative delicacy of tests for copper in solutions, Dr. Van Slyke said that the first test was that given by an excess of ammonia in a solution containing copper, thus producing a blue color. It will show one part in 25,000 parts of water. Potassium iodide gives a yellow tinge to a solution containing one part copper to 50,000 parts of water. Potassium ferrocyanide, as used in making Bordeaux mixture, detects one part in 400,000 parts of water. Potassium zanothate (a chemical seldom found outside the laboratory), added to a copper solution, will give a dense yellow color that will show in a solution of one part copper to 800,000 parts of water.

The most delicate test of all is that made by immersing any ordinary needle, wrapped with platinum wire, in a solution containing copper. An electric current will be set up and the copper will be deposited on the wire. The ferrocyanide test is so delicate that if it is properly used in making Bordeaux mixture there will be no copper left to hurt the foliage. The ferrocyanide should not be poured into the mixture until after the lime has been thoroughly stirred in.

An investigation was made concerning the relative quantities of potash and phosphoric acid required by fruit-trees, fruit and nursery-trees. As an average each tree used one and one-third pounds of potash for one pound of phosphoric acid. The fruit averaged four pounds of potash to one of phosphoric acid, while nursery stock required sixteen and a half pounds of phosphoric acid to thirty pounds of potash to the acre, the extremes of phosphoric acid being from ten to twenty pounds, and of potash seven to forty-eight. From the above it will be seen that the orchardist needs to use a larger proportion of potash than comes in ordinary commercial fertilizers. He had written to a large number of firms for prices on single fertilizing ingredients, and found most of them willing to sell these separately, though generally recommending their mixed goods. He advised buying dried blood in Chicago, as it was less liable to be adulterated than after it had been sent to New York, where large quantities of leather scraps mysteriously disappear presumably into dried blood.

A PRACTICAL VIEW OF SPRAYING.

Mr. Albert Wood, of Orleans County, said he had an orchard of twenty-five acres on a gravelly loam. The trees were too close at two rods apart. The shaded ground became mossy; the red apples showed little color. He went through the orchard and cut out every other tree six years ago, since which time he has cultivated and fed those that were left. In 1893 he sprayed two trees; on these the apples were good, while most of the others went to the dry house. On the 20th of April, 1894, he sprayed his orchard, except fourteen trees left for comparison, with twenty pounds of copper sulphate, four pails of lime and 150 gallons of water. He sprayed again as the buds were swelling, and again when the apples were half an inch in diameter. About this time the apples on unsprayed trees began to drop. With the last two sprayings he used Paris green—one pound to each 150 gallons of water. On the fourteen trees not treated the foliage was rusty. The thirty-five barrels of fruit he picked from them shrank five barrels between picking and selling. Of the 2,000 barrels of treated fruit the shrinkage was not five barrels in the same time, and they brought thirty-eight cents more a barrel. On a Strawberry Apple-tree that had not had a perfect apple in nine years every apple was sound. Similar results were had with King, Baldwin and Twenty-oneounce trees. Of Roxbury Russets three-fourths of the untreated apples were ground for cider, while most of those treated were good. Roxburys should have five sprayings a season.

Pears were treated in the same way as the Apples. Some Virgalieus had borne no perfect fruit for twenty-five years, and this year, when sprayed, there was no imperfect fruit. His results showed ninety per cent. gain by spraying. In a young orchard-row not treated the leaves fell three weeks earlier, and the foliage was not as heavy as on the sprayed trees. He had similar results with treated and untreated Cherry and Plum trees. From Fay's Currants which had been sprayed he picked fruit twenty days after others were gone. He thought the Bordeaux mixture should be applied as a mist, and that the Vermorel nozzle was best except for the higher trees, where the McGowan was the best. A tree should be sprayed till it drips. You cannot throw Bordeaux mixture far when reduced to a fog, and, therefore, for large trees long bamboo-poles must be used to hold the nozzle close to the foliage. He used 900 pounds of copper sulphate for thirty days' spraying.

PEACHES AND APRICOTS IN WESTERN NEW YORK.

Mr. Nelson C. Smith, of Geneva, said that these fruits could be successfully produced with proper study and care. It will not answer to trust to luck for fine fruit, and fancy fruit alone brings fancy prices. It is a greater drain on a tree to produce two bushels of second quality fruit than a bushel of extra-fine fruit. When the trees have done their work, it is necessary, if the highest price is secured, to pick the fruit at the critical moment when it is just ripe enough, but not too ripe, and then it must be packed in small, neat packages.

The soil best adapted to Peaches is a rich mellow loam with a clay subsoil, preferably high and rolling, near large bodies of water. Half of the previous season's growth should be shortened in every year and cut so as to make a fine-shaped head and kept well supplied with bearing shoots. At six or seven years old it will not need severe cutting.

The thinning is the most neglected of all the operations of Peach-growing. The fruit should be thinned to five or six inches apart. Some persons believe it costs too much to thin, but the fruit must be picked some time, and in this instance the early picking more than pays in the increased value of the later one, not to speak of the saving of strength to the trees.

Apricots are now known to be hardy on the eastern bank of Seneca Lake, and they are considered better than California fruit. The Early Golden has produced fifteen crops in twenty years. The so called Russian varieties are no more hardy than many others, and are poor in size and quality. Apricots need a dry soil and treatment similar to Peaches. The essentials for success are a good location and soil and persistence in fighting the curculio. It requires judicious marketing and pluck, if any fruit does. It demands severer thinning than any other fruit, for if the fruit is allowed to remain this will check the growth of the tree, and the fruit-buds are formed on the new wood. Myrobalan and Marianna stocks are best on heavy soils, and Apricot for light soils.

To a member who asked why his Duchess pears rotted in the ice-house in September, Mr. Barry replied that the trouble was usually caused by picking too early. He considers it best to leave Duchess, and even Anjou, on the trees until the

third week in October—that is, to leave them on as long as possible. When they are picked too early they shrivel. Mr. Bell thought it better to leave Duchess pears on the tree even till a frost touches them than to pick them before the second week in October. Light frost will not injure them. Mr. Morrell, of the Michigan State Horticultural Society, said that trees well fed with phosphoric acid and potash will hold pears two or three weeks longer than those not so fed, and the pears will grow wonderfully during that time.

In answer to a question as to how to build a cold-storage house, Mr. Lyons described some successful ones as having brick or stone walls for a part of their height, with a double-boarded frame of eight-inch studs above, the space between the boards being filled with sawdust, and the whole then ceiled inside and out. There are no air-spaces in the brick wall. The buildings are cooled by opening and closing the doors and windows in accordance with the outside temperature. Mr. Boag, of Batavia, spoke of his having two sixteen-inch walls of stone, with a two-inch air-space and double floors. There were ventilators at the bottom and in the roof. Two years ago he kept apples till May in good condition, while many had trouble with mildew.

Mr. Woodward had fruited the Crosby Peach two years. The trees were productive and ripened fruit a little earlier than the Smock and after Late Crawford. This peach has a small pit, fair flavor, and is not large, but fairly handsome. The tree is a poor grower. On the whole, he is well pleased. Another member stated that all the fruit-buds on Crosby trees were killed in his orchard, but this was also true of other varieties.

Recent Publications.

A Practical Flora for Schools and Colleges. By Oliver R. Willis, A. M., Ph. D., New York. American Book Company.

What Dr. Willis means by a practical flora is explained in the preface of this book to be one which "shows the practical aspects of the vegetable world and its relation to the needs of every-day life, for the purpose of engaging the interest and the enthusiasm of such pupils as do not have the scientific mind which makes the acquirement of the science an end in itself, nor the poetic temperament required for the love of the study for itself." In carrying out his design for arousing effort on the part of students whose mental endowment is somewhat restricted, Dr. Willis has added to the ordinary scientific description of plants generally found in school botanies some account of the economic features and the history of the different species. Since there are few plants which do not have some qualities which are useful, or hurtful, or ornamental, it is evident that the selection of these so-called practical notes should be very carefully made if the work is to have any proportion or symmetry, especially since the flora and its practical annex are contained within the limits of three hundred pages. In this selection we do not think that Dr. Willis has been altogether happy. Sometimes he goes into details which hardly seem attractive to the boy who does not love science for its own sake, as, for example, when he states that opium, the product of the Poppy, "is a very complex substance, containing a large number of bases in combination with sulphuric and meconic acids. Morphine, whose formula is $C_{17}H_{19}NO_3$, and narcotine, whose formula $C_{22}H_{33}NO_7$, are the most abundant and important," and to these he adds the formulas of codeine, thebaine, papaverine and narceine, which need not be repeated here. Excursions like this into the realms of organic chemistry might easily make a very large and repulsive work for pupils with no hunger for exact science, but at times these notes are much more popular as, for example, when he states that "no other small fruit is more generally cultivated than the currant, which is not only grown in the gardens of the rich, but is also to be found in the planted ground of the most humble cottager." The information that for "pies, puddings, dumplings and preserves the peach has no equal," does not err in being too profoundly scientific, nor do recipes for making apple butter or quince preserves. In other words, Dr. Willis's practical flora is encumbered

with much information which young pupils in botany cannot digest and assimilate, a great deal more that they do not need to be told, and very little which cannot be found in better form in the nearest cyclopedia.

Notes.

We have received a series of twenty pictures from different points of view of Mr. S. C. Nash's water-garden at Clifton, New Jersey, which has often been mentioned in this journal. These prints are from photographs taken by Mr. Nash, and they have been reproduced by the photogravure process, so that none of the delicacy of the photographic detail is sacrificed. The pictures not only give a good idea of such plants as the *Victoria regia*, the various *Nymphaeas* and *Nelumbiums*, but they convey instructive hints to any one interested in aquatic gardening, especially in the important matter of planting along shores, and thus furnishing a proper setting for lakes and ponds. Mr. Nash has a few extra sets of these views which he will dispose of at less than their original cost.

In *Meehan's Monthly* for February the sound advice is given to dig a trench before spring growth begins around large trees which are to be moved. The inside of the trench should be two feet from the butt or more, according to the size of the tree. It should be deep enough to cut off most of the roots, two feet at least, and the trench should be carefully filled up with good soil, which should be firmly packed about the ball. Next autumn many new roots will have been formed, and the transplanting of the tree will be much more easy and more certainly successful. When the trench is dug, the top of the tree should be pruned back, though not as severely as if the planting was to take place immediately. Mr. Meehan says that some large Scarlet Oaks and American Beeches treated in this way last winter made a very remarkable root-growth during the following summer.

The literature of spraying is becoming very extensive, and no one who wants to apply remedies against insects and fungi in this form need lack for information. Bulletin No. 74 of the Geneva Experiment Station gives a very complete account of the machinery for this purpose, but it is said that better machines are still needed. For Potatoes and Tomatoes a nozzle should be used which can be lowered between the rows and directed so as to spray up through the vines. The same sprayer should not be expected to do all kinds of work with equal satisfaction. The agitator, which keeps the mixture of uniform strength by preventing the heavier ingredients from settling, is one of the most important parts of any sprayer and one which works up and down like a churn dash is the best. Pumps for spraying should be made of brass, or should be brass-lined, and when the piston-head is packed the packing should be frequently changed.

A writer in a recent number of the *Gardeners' Magazine* gives an interesting account of the cultivation of Kent Cobnuts. The particular orchard, if such it can be called, which he describes, covers something like sixteen acres, and was carrying, at the time of the writer's visit, about thirty-two tons of nuts. Some of the trees on this farm are seventy-five years old, and in the rich deep soil of West Kent the stems of many of them are eighteen inches in diameter and gnarled with age. These trees are usually called basin-shaped, but an ordinary sugar-basin with a short stem more truly represents their shape. The stems are from fifteen to eighteen inches high, and the branches radiate from these in an outward direction to a distance of from four to seven feet on each side, and by a perfect system of training and pruning they form a complete circle eight to fourteen, or even more, feet in diameter. The trees are trimmed to a flat top some five feet high, and to one looking across the great plantation not a branch is seen above this line. By summer and winter pruning these trees are kept in this shape, and the branches are closely covered with spurs, from which the nuts are produced. No suckers are seen, and something like three hundred trees may be grown on an acre, but the number varies according to the size. Many of the trees will produce ten pounds of nuts.

In the autumn of 1893 we mentioned the fact that the so-called Rose-colored Calla, *Richardia Rehmanni*, had flowered in Holland, and that the spathes as they appeared there were described as white, tinted with rose. In one of Mr. Watson's letters of January of last year it was stated that a colored picture of the plant as it grows in Natal showed that there is a variety of the plant there with spathes of dull rose-purple. In October last we gave an account of the flowering of the plant in Kew, where it showed nothing more than a flush of rose-

color inside of the upper portion of the spathe. The last number of *The Garden* gives a picture of this plant in flower from a photograph sent from Holland, from which the appearance of the plant is shown to be quite different from the ordinary Calla, although it is a true Richardia. The distinct feature of the plant, as we have noted, is the lanceolate form of the leaves, which resemble somewhat those of a Canna, and the spathes are striped, as they unfold, in a way which reminds one of Jack-in-the-pulpit. The color of these stripes is said to be chocolate-brown, while on the inside the spathe is said to be a soft rose-color. It is suggested that the difference between the color of this flower and of the flower of the Kew plant may be due to the fact that one came from a much more southern latitude than the other. It is not improbable that the Rose Calla needs a hot sun to bring out its distinctive color, and it might do its best in our southern states. It is plainly less desirable than the white Richardias, and even than the yellow-spathed species. Nevertheless, it may be useful for hybridizing, and may found a race with a range of color quite distinct from any we now have.

At the semi-monthly meeting of the Massachusetts Horticultural Society, on February 2d, there was a fine display of cut blooms of Orchids from the Ames collection at North Easton, including first-rate examples of white forms of *Lælia anceps*, one called *Vestalis* being remarkably good, and another called *Winniana*, one of the darkest of all the varieties of this winter-blooming *Lælia*, was specially good. Mr. Robinson, the gardener, also showed a fine hybrid *Cypripedium* of his own raising, and named after Mrs. F. L. Ames, a cross between *C. Fairieanum* and *C. tonsum*, the latter being the seed parent. The hybrid showed plainly the parentage, having the characteristic petals of the charming pollen parent, with the shining surface over the whole flower that is so marked a feature of *C. tonsum*. Another hybrid raised in the same collection was shown, it being the North Easton variety of *Cypripedium H. Ballantine*, a charming little plant, having for its parents *C. Purpuratum* and *C. Fairieanum*. There were also a collection of cut blooms of Orchids from Mr. John L. Gardiner, of Brookline. Cut blooms of Camellias were also shown in quantity, chiefly by Francis B. Hayes, and made a fine display. The competition for the prizes offered for Violets was good, and the first prize was well merited by those shown by Mr. W. N. Craig, of Taunton, but the two vases of Marie Louise, shown by Alexander Mackay, of South Framingham, were, perhaps, the largest of their kind ever shown in Boston, the flowers easily covered a silver dollar, and the color was superb, eclipsing all other varieties on exhibition. There was also another promising kind, shown under the name of the Farquhar. A good display of Carnations was staged, the first prize going to the noted specialist from Framingham, Mr. W. Nicholson, and the second prize to Mr. W. N. Craig.

The second period of freezing weather in Florida was even more disastrous to the Orange groves than the first, when, as we have stated before, the crop of fruit was practically destroyed. The older trees, which had not been killed, had begun to put forth leaf-buds and fruit-buds, and this second cold wave has evidently destroyed these and apparently ruined the next crop. The cold weather has also hurt the crop in Spain, so that now nearly all the oranges in this market are from Sicily and Jamaica. From the latter island some very good fruit is coming, and this is here repacked in boxes like those used in Florida. The California orange season practically begins when the Florida season ends, in February, and continues through the spring months. Of course, the short crop elsewhere will make prices of California oranges high, so that this season's crop in that state will be unusually remunerative. The best California Navels which are now here seem to be of unusually good quality and they sell by the box for \$2.50 to \$4.50; good ones bring sixty-five cents a dozen. This unprecedented cold weather throughout the south has disorganized the vegetable market, and the supply here comprises hardly any fresh green vegetables besides the ordinary northern winter sorts and limited quantities of a few kinds from northern hot-houses. Hot-house tomatoes cost from sixty to eighty cents a pound; new carrots, forty cents for a dozen bunches containing five of these small but tender vegetables; radishes cost five cents a bunch, and tiny fresh onions the same price. Kohl-rabi, from Bermuda, rhubarb grown under glass on Long Island, and very slender stalks of hot-house asparagus, costing \$1.25 for a small bunch, are other luxuries seen in the best markets. The heavy snows have seriously interfered with transportation, and the large supplies of kale and spinach which come from Norfolk, Virginia, have been cut off for the time.

Defacement of Parks in Buffalo.

IN the annual report of the Buffalo Park Commissioners for 1891 the Superintendent complained that in the various minor squares, and to a certain extent in the larger parks, the plantations were suffering serious injury not only from thoughtless trespassing, but from purely malicious mischief. This complaint has been repeated by the Superintendent in every successive report, and in that for 1894, which has just come to hand, the Commissioners themselves say that in The Parade the greensward is so cut across with beaten tracks and the general aspect of the grounds is so shabby and forlorn that the place is an offense to the eye and an affront to common decency. But, worse than the destruction of the park, is the debasement of the public sense of right and wrong in this matter, for the Commissioners declare that it is useless to attempt any renovation of the place until a higher standard of public duty has been established. Trees, shrubs and plants are mutilated in broad daylight, lawns are seamed with ragged paths, outrages against common decorum are committed, and park ordinances are contemptuously ignored. Inasmuch as there are only seven patrolmen for the whole park system of the city, whose business it is to preserve order in as many widely separated parks, the police force is evidently not responsible for this lawlessness. And, even when arrests are made, public sentiment, expressed through the courts, sustains petty trespassing, and the offender knows that if he is arrested the Judge will be as likely to reprimand the patrolman for making the arrest as to punish the offender for the destruction of the public property. Under such conditions, all attempts at creating or maintaining anything like landscape beauty is a mockery, and all money spent for this purpose is worse than wasted. This vandalism is worse in one park than in others, but it is gradually spreading to all, so that, in the language of the report, "the standard of keeping for all the parks must finally be such as can be maintained on the sufferance of the meanest vandals of the community."

When the project of building a park in the centre of Manhattan Island was first suggested, some good men considered the scheme preposterous, because, as they asserted,

it would certainly be made the field for the rough sport of the more depraved elements of the community. Wiser men held that a beautiful piece of scenery would largely be its own protection, and such a public regard for it would soon develop, that protection from thoughtless or malicious injuries could easily be secured. Of course, the city did not begin by putting a hundred acres or so of park land under the control of a single policeman, for wherever there is a proper regard for any pleasure-ground there will be a public sentiment which will ensure an adequate force for its safety. But at the very outset there never seemed to be a disposition to deface Central Park, or if there was, prompt suppression in the beginning prevented the growth of such a lawless sentiment. This has been the experience of most American cities. In San Francisco, where there are more showy flowering shrubs and trees in the parks than there are in any other American city, we have never heard of any trouble of the kind. There is no such trouble in Boston in the parks or in the Public Garden; there is none in Brooklyn, none that we ever heard of in Philadelphia or Baltimore. Even in Chicago, where the original design of the parks has been ignored, and where some of the ground has been treated in the most vulgar way by the managers, the condition of things is not so bad as it appears to be in Buffalo from the report of its own officers.

It is not to be assumed that the people of Buffalo are less law-abiding than the inhabitants of other cities, but in this one particular the community offers a striking example of the demoralization which invariably comes when offenses, which seem trivial at first, are permitted, until their constant repetition without reprimand or punishment invests them with the character of privileges and inalienable rights. The trespasser justifies his action by the statement that the people own the parks and, therefore, the people have a right to use them as they choose. The correct statement of his reasoning is that since all the people own the parks, therefore any one of the people can do with them as he pleases, and this is the essence of anarchy. The popular cry against boundary fences as obstacles which prevent the people from enjoying the parks—that is, barriers which prevent one man from entering the city property at any point he may prefer—and the cry for the free use of the turf because everybody owns the park meadows, and, therefore, anybody has a right to walk upon them, are both examples of this individual self-assertion which does not recognize the fact, which is the basis of civilized society, that a community has an organic life of its own, and that each man owes it respectful and loyal obedience. Every sensible man in Buffalo knows this, but there are some people in that city who have walked where they pleased so long that they now resent as a violation of their natural rights any attempt to restrain them from making paths across the turf, and the persons who have been permitted to break shrubs and carry away flowers for a time have come naturally to believe that the shrubs are planted for this purpose exclusively.

It seems that there was once a wooden fence, which in some measure protected one park from wear and defacement. When this began to need repairs it was broken at every point where any one wished to enter or cross the ground, and public sentiment had become so firmly set against a fence that no appropriation could be obtained for one. Of course, the park is completely wrecked, but the debasement of public morals is much more serious than the damage to turf or trees, for this generates and develops a spirit which ultimately makes all public property unsafe. The enlightened people of the town must realize that something should be done promptly to regenerate the public morality in this particular. Such a sentiment ought to make itself quickly felt by strengthening the protective force of the parks and by compelling judges to enforce laws against trespassers. It will be much harder to do this now, since these laws have been so long violated with impunity. But a beginning should be made at once. The public parks of our country in rapidly growing cities

are subjected to enough dangers, at the best, from threatened invasion and confiscation. But where the people stand by and see well-planned and beautiful parks turned into desolation, and property of unspeakable value to rich and poor laid waste, without any attempt to arrest the injurer, and even without protest or indignation, the case seems almost desperate. When parks become utterly abandoned and left a prey to trespassers, it would be a wise policy to run streets across them, cut them up into building lots, sell them off and put the money in the city treasury.

We have received a chart of life-size pictures of the leaves of some of our native Oaks, and the drawings give proof of accurate observation of the subjects in all stages of their growth. This tree-leaf chart is printed on good paper, and a prospectus gives the information that others are to follow, containing the leaves of other families, and including the most valuable deciduous shade, nut and timber trees, native and foreign, which are adapted to our northern and middle Atlantic states. If these charts could be hung up in the school-room they would be an admirable help to pupils who wish to identify the various species and varieties of trees about them, and a skillful teacher could make a great use of them in encouraging habits of observation among the young. They would not only be useful in the school-room, but in the family circle, and they would familiarize children with the various forms of leaves and help to interest them in the study of our native trees. The drawings are made by Grace Anna Lewis, of Media, Pennsylvania, and the charts are sold at the moderate price of fifty cents each.

Botanical Notes from Texas.—XXIV.

CHEROKEE COUNTY lies in the central portion of eastern Texas, and a few years ago it was prophesied that its capital town, Rusk, was to become the chief iron-manufacturing city of the south, if not of the United States. Much money was spent in erecting furnaces, hotels and long brick blocks, and streets were laid out for long distances through the surrounding country, but the fires have gone out in the furnaces, while hotels, business houses and many dwellings are deserted. Valuable ore of iron is here in great abundance, it is true, and later on it will be brought into use, but the markets of the world do not need it yet.

This county and the adjoining ones are, perhaps, the best peach-growing region in Texas. A hundred car-loads of this fruit were shipped from Jacksonville alone last year, besides supplying the canning factories there. This is a small amount, it is true, but the industry is young yet. The best fruit-lands here are on the sandy tops of the iron hills; there the young fruit escapes injury from early frost, while in the valleys it may wholly be destroyed. This branch of horticulture is capable of indefinite profitable extension throughout eastern Texas. The practice of raising Peach-trees, largely from seeds, has developed many varieties of excellence hardly anywhere surpassed. The latent energies of the Peach, even after so many centuries of cultivation, is not easily to be overestimated. A species, that by a bold and successful effort at bud-variation, could develop so remarkable a variety as the Nectarine, is liable to perform still greater wonders in the future.

As the tourist goes over Texas he is surprised to see to how great an extent Cotton is still the field-crop of the state. The season of cotton-picking extends over the last six months of the year. The entire cotton product of Texas aggregates an immense sum of money for the state; that amount, divided among the owners of four millions of acres of land and the renters of it, the laborers, the pickers, the ginners, the oil men, the weighers, the buyers, the commission men, the railways, the storers and the shippers, does not leave a large sum for any of them. Those who fare the best seem to be the landowners, who are generally merchants, bankers or men of other professions living in

the cities, and those who handle the crop after it is raised. Profitable or not, the present condition of affairs will only slowly change. Cotton is the surest money-crop of the south, and, therefore, many farmers are obliged to raise it, even though they buy the necessities of living, which they might otherwise raise for themselves.

Witch Hazel, *Hamamelis*, is not so distinctively a fall-flowering shrub, as some botanists have written it. Differences of climate and soil may change the living ways of plants, as they change the living ways of animals and of men. A long residence in Texas has taught the Witch-hazel that it need not blossom in the fall, that it will have time enough to effect fertilization and to ripen fruits and seeds in the same year, and therefore the flowering is put off until February, and even later, and then have time to perfect seed before the year closes. That peculiar Sunflower, *Helianthus angustifolius*, abounds in eastern Texas from the Gulf to Red River. An interesting feature of the woods of this section in the early fall is the handsome fruit of French Mulberry, *Callicarpa*. A wine, or more properly a cordial of successful intoxicating quality, has been made from it.

One day as I was walking along one of the railways leading out from Jacksonville, I recognized the fragrance of the Sweetbrier, and soon saw a lusty plant of *Rosa rubiginosa* by the wayside. It was the only individual of the species that I had seen in Texas. It is rarely found wild in Kansas. In New York it is common along roadsides. *Lobelia puberula* is common here in damp places. It resembles *L. siphilitica* more than any species of the genus, but it is taller and slimmer than its congener.

The handsome Pink, *Spigelia*, is frequently seen in this county. It is the Pink of the medicinal firm of Pink and Senna, and the species, for its beauty, is worthy of a place in the wild corner of any garden.

Solidago odora is the commonest as well as the handsomest Golden-rod of eastern Texas, and often three to five feet tall. It is handsome enough for any garden, and pleasantly and so strongly odorous as to fill the air with its fragrance. Of our native species of *Solidago*, *S. tortifolia* resembles it most closely.

I met *Hydrolea affinis* near Jefferson, for the first time in Texas. *H. ovata* is much more abundant. They are rather handsome plants with spiny stems and bright blue flowers. The last-named species has a very downy calyx, a character which its congener does not possess. The Wild Turnip, *Arisaema*, Jack-in-the-pulpit, grows in this vicinity by the side of its homelier but commoner congener, *A. Dracunculus*. The family garden has no longer a corner for medicinal herbs, and strings of wild turnips no longer adorn the chimney-corner, for, though we are told that those bulbs lose all their virtue in drying, yet grated and mixed with honey or maple-molasses they were once thought to be a sovereign remedy for colds and coughs, especially in the case of children. In those earlier days, too, when the tea-canister was empty and the supply of coffee had been exhausted, the same closet contained dried roots of Water-avens, *Geum rivale*, a decoction of which, drank with milk and sugar, was no mean or unpleasant substitute for the costlier drinks.

Among many distinguished tree foreigners who have taken out naturalization papers in the United States, some of whom are living in eastern Texas, is *Paulownia imperialis*. That species has been largely planted for ornament, and has quickly run wild. Foreign plants as well as foreign people are rapidly taking possession of many parts of the country. We are loath to admit the Chinaman, but we freely admit the China tree to naturalization, and not only *Melia*, but also *Paulownia*, *Ailanthus*, *Sterculia*, *Stillingia*, *Albizia* and others. The new forests of the south are likely to be largely of Mongolian extraction. It is strange that so unique and handsome a foreigner as *Ginkgo biloba* is seldom, if ever, seen on Texas lawns.

Two humble Asiatic plants, that probably came to the United States uninvited, are working a silent but important

change in southern agriculture. Those plants are Bermuda Grass, *Cynodon Dactylon*, and Japanese Clover, *Lespedeza striata*. Pity it is that part of the common name of the last-named species should be a misnomer, as the plant is not a Clover. Both of those plants have largely spread over the more eastern Gulf states. They will soon cover most of Texas. They are hardy and excellent forage-plants. Bermuda Grass, as a plant fully able to take good care of itself, will prove a great boon to the farmers of Texas. As a food for all live stock, as a shelter and a fertilizer of the soil, to hold the dew and the rain, and to prevent washing of soils and embankments, it has no superior. It is no wonder that in its native India, where it is more needed even than in Texas, the Hindoos rank it among their plant gods, and ascribe to it terms of reverence and worship. There have been many meaner things worshiped than Bermuda Grass.

London Letter.

NOTES ON ARISÉMAS.—A collection of these plants makes an interesting feature at Kew during the early months of the year, when most of them flower. Over twenty species are represented, out of a total of about fifty, which are distributed over the temperate and tropical regions of Asia, chiefly the Himalayas, and one is North American. Some of these deserve to rank with good garden-plants, though as yet they have received little attention from horticulturists—in Europe, at any rate. All the species have tuberous root-stocks similar to the Caladiums, which they also resemble in losing their leaves and resting for a period every year. In some species the leaves are folded at the base, so as to form a sort of stem, and the blade is trisect or pedate. In form and coloration the leaves are generally ornamental, the stalks being mottled or striped, and the leaflets margined with pink or brown. The inflorescence is in the form of a trumpet or funnel, one side being prolonged to form a long flap or hood, the tip of which is sometimes a long hair-like tail. In color the spathes vary, some being green and brown, others purple, with white stripes, others red-brown, and so on. The spadix in some of the species is often very long and filiform, and sometimes is clothed with long setose hairs. The flowering season extends over about two months. None of the species have a disagreeable odor when in flower. A vase filled with a collection of the flowers of Arisemas is a pleasing and uncommon object. The plants at Kew are started into growth in January, when the tubers are shaken out of the soil in which they have been at rest since the leaves died away in July or August, when they were placed under a stage in a cool greenhouse. The tubers are cleaned as if they were Caladiums, and then potted, either singly or several together, in a mixture of peat, loam, leaf-mold and silver sand. The tubers are buried two inches below the surface, and the soil only slightly pressed about them. They are then placed on a tan or cocoanut fibre bed in a greenhouse where the atmosphere is moist and the temperature falls to about fifty degrees in cold weather. As soon as the growths push through the soil the whole should be well watered and afterward kept moist, these plants being, if anything, swamp lovers in a state of nature, as, indeed, are all tuberous-rooted Aroids of which I know anything. Should the fleshy white roots push above the surface of the soil a top-dressing with cow-dung and loam may be given. When the spathes open, the plants may be placed in the conservatory or a cool greenhouse. When the flowers fade, the plants should be encouraged to keep green as long as possible, so as to insure good tubers for the following year.

The American Indian Turnip, or Jack-in-the-pulpit, *Arisëma triphyllum*, grows well, and flowers annually here in a border against a south wall outside, its companions being the Sauromatum and Arum crinitum. These are left in the

ground undisturbed year after year, and never suffer from cold. The position is one where the soil is always rather moist, a condition that appears to suit them.

The following are the best of those species grown at Kew during the last ten years:

ARISÉMA SPECIOSUM.—This is a beautiful plant, and as easily cultivated as a tuberous Begonia. It is a native of the Himalayas at from seven to ten thousand feet, and was first introduced in 1872, when a figure of it was published in the *Botanical Magazine*. It has since been figured in the *Gardeners' Chronicle* and *The Garden*. It produces one, sometimes two leaves, the petioles of which are two feet long, brownish green, with whitish marbling; the blade is tripartite, the leaflets each a foot or more long, nearly half as wide, narrowed at the apex to a tail-like tip, wrinkled and colored dark green, with a reddish margin. The spathe is erect on a stalk about half a foot long, and measures from the base to the top of the hooded portion six or eight inches, beyond which there is a tail two inches long. The spadix for four inches from the base is as thick as a man's little finger; beyond that it is a thin filamentous tail from one to two feet long. The color of the whole is rich vinous-purple, with lines of grayish white running from the base of the spathe upward. The purpose of this tail attached to the spadix and reaching to the ground is supposed to be to lead crawling insects up to the flowers to aid in fertilization. A remarkable character in this species is that of being sometimes monoecious and sometimes dioecious. It ripens seeds under cultivation.

ARISÉMA FIMBRIATUM was introduced from Penang in 1884, when figures of it were published in the *Botanical Magazine* and elsewhere. Recently Messrs. Sander & Co. have imported it in quantity. It has a solitary leaf, three ovate acuminate-tailed leaflets of a rich green color borne on a red-brown petiole a foot long. The spathe is six inches long, hooded, the lower portion light green, with white stripes, the upper purple and white; the spadix is thin and tail-like, hangs down to a length of six inches, and is clothed with blackish bristle-like hairs an inch long. This species requires stove treatment always.

ARISÉMA FILIFORME is a Malayan species of recent introduction. It has pedate leaves, the leaflets lanceolate-acuminate, sometimes a foot long, the petiole red-brown, with gray marbling. The scape is two feet high and bears several smaller caudine leaves; spathe-tube two inches long, green, shading into brown; limb five inches long, two inches wide, hooded and colored dark brown, with a metallic-green shade; spadix six inches long, the upper portion narrowed into a smooth brown tail-like appendage. Though wanting in brilliancy of color this is a handsome stove plant. It should be always kept in the stove and moist. At Kew it does not die down, in which respect it resembles *Richardia Æthiopica*. I do not see any difference between *A. filiforme* and *A. Wrayi*, of which there is a figure in the *Botanical Magazine*, t. 7105, beyond that of color, the spathe of the latter being pale green, almost white in places, and the tail a little longer. They are alike in habit and stature and in behavior under cultivation. Both of them are in flower at Kew now.

ARISÉMA GRIFFITHII-HOOKERIANUM was introduced and flowered in 1879 by Mr. H. N. Elwes from the Sikkim, Himalaya. There is a figure of it in the *Botanical Magazine*, t. 6491. It has a large tuber, usually two leaves, the petioles of which are a foot long, half an inch in diameter, smooth and green; the three leaflets are nearly a foot long, six inches wide, dark green, tinged with yellow along the margins. The flower-stalk is short, and it bears an erect spathe, which is tubular below and colored black-purple, with paler stripes; the upper portion is hooded six inches across and curiously inflated on each side, suggesting the puffed-out shoulders of a lady's dress of the present fashion; this portion of the spathe is dark purple, with green reticulating veins. The spadix is thick at the base and elongated above into a hair-like appendage, which is sometimes three feet long. This is one of the most remarkable

plants in the order, the structure of the spadix being as singular as that of the pitcher of *Darlingtonia Californica*.

ARISÆMA MURRAYI was introduced from Bombay in 1847. There is a figure of it in the *Botanical Magazine*, t. 4388. It has large, potato-like tubers, a solitary leaf, the stalk of which is eighteen inches long, green, mottled with red-brown, and the leaflets are oblong-acuminate and six inches long; the spathe is five inches long, with a green tube, the upper portion white, curved over and forming a hood, the sides of which are purple. The spadix is short and wholly enclosed in the spathe.

ARISÆMA UTILE is a native of the Himalayas, whence it was first introduced in 1879. It resembles *A. Griffithii* in all its characters except that the spathe is smaller and is chocolate-brown in color. By some the two are considered to be only forms of the same species. Sir Joseph Hooker found it at an elevation of 13,000 feet in Sikkim; it may therefore be hardy, but I have never seen it tried out-of-doors. Sir Joseph Hooker says it is the commonest species in Sikkim, where its tubers are used as food by the hill tribes after they have been macerated and boiled.

ARISÆMA NEPENTHOIDES is another Himalayan species which was first cultivated here in 1879. It has a large turnip-like tuber, leaves two feet high, with the blade divided pedately into five oblong tailed leaflets, and the stalks colored green, with dull red blotches. The flower-stalk is nearly as high as the leaves, and the spathe is erect, six inches long, shaped somewhat like the pitcher of a *Nepenthes*, colored brown, the upper portion folded over, forming a tailed flap, colored yellow-brown, the ears green and brown, with dark spots; the spadix is erect, shorter than the tube and whitish in color. This is altogether a pleasing plant in the singular coloration and elegant form of its spathe. It is very easily kept in health.

ARISÆMA RINGENS (*præcox*) is a Japanese plant which has long been in cultivation here in the gardens of the curious. At Kew it is planted among Sikkim Rhododendrons, etc., in the large temperate house, where it produces very large lustrous green trifoliate leaves and large hooded flowers, which are green, with white stripes on the outside, black purple, with white stripes inside. The top of the spathe is folded over and then contracted, so as to form two round window-like apertures, one on each side.

W. Watson.

London.

duced thirteen leaves from the small corms which this species appears to produce freely, like several other *Gladioli*, on top of the old corm. The leaves were about two and a half feet long, and six of them bore flowers, indicating the free-flowering quality of this species, which is certainly one of the best winter-flowering decorative plants which have come under our notice for a long time. Its free habit and the size, beauty and fragrance of the flowers should commend it to florists as a good companion for the Freesia, which this *Gladiolus*, although it does not produce so many flowers on a stem, surpasses in their size, form and coloring. It grows so freely in a low temperature, too, and can be had in flower so early in the winter, that it would be a cheap plant to raise; and it is not improbable, too, that it would make a good house-plant, although on this point we speak without experience.

Plant Notes.

BORONIA MEGASTIGMA.—In the early volumes of GARDEN AND FOREST we frequently called attention to this Australian shrub particularly for the delicious, and yet intense, fragrance of its flowers. At this season one or two plants will perfume a very large greenhouse, and a spray or two will pleasantly scent a large room. This shrub is about two feet high, the main branches being erect, and the opposite branchlets spreading, with flowers borne in the axils of the sparsely set narrow leaves. They are bell-shaped or semi-globular, solitary and pendulous, half an inch in diameter, of a reddish chocolate-brown, or, as the catalogues say, maroon-purple on the outside, and clear yellow within. In a general way it may be said that this *Boronia* needs a cool-greenhouse treatment, like the Cape Heaths, but when grown from cuttings these should be taken from the branches somewhat hard rather than the more sappy ones, and as the plants do not require much root-room small shifts are the best. When the plants are done flowering they are cut back, so as to make thick, stocky plants, and it is well to stop the shoots often to prevent them from running up into thin and rather scraggly specimens instead of well-furnished and compact bushes. It is essential that the pots should be well drained as they are shifted on, since stagnant water is very injurious. During the summer these pots can be plunged outside in a position where the midday sun does not strike them. Mr. Robert Cameron writes from the Harvard Botanic Garden that he takes cuttings from the moderately hard growth, plants them in four-inch pots which are filled with a compost of finely sifted loam, peat and sand to within an inch of the top of the pot. Over this is spread a layer of very sharp sand. When the cuttings are inserted they receive a thorough watering, and are then placed under a bell-glass in a greenhouse where the temperature ranges from forty-five to fifty, and are kept shaded from bright sunshine. The plants blooming in the Botanic Garden now, however, were raised from seed sown two years ago. Seeds germinate readily in the same temperature required for cuttings, and they soon make nice plants. A few years ago it was noted in this journal that Mr. C. M. Atkinson tried the experiment of cutting these plants back severely in spring and planting them out in the open air. They seemed to make a stronger and healthier growth than those kept in pots, and they flowered equally well.

CESTRUM ELEGANS.—The flowers of this rather old-fashioned plant are very attractive in the cool greenhouse just now. When grown in large pots, the plants make shrubs five feet high. The long arching branches, with their ovate lanceolate leaves, are terminated with large dense cymes of purplish red flowers. Besides its value for decorating the conservatory, the sprays are good for cutting. In spring the plants should be cut well back and repotted, and in May plunged outside in the garden, where they make good growth during the summer. They are taken back to the cool greenhouse in the fall, where they give a quantity of flowers during the dull months of winter. This *Cestrum*

New or Little-known Plants.

Gladiolus tristis concolor.

THIS plant, of which a figure is published on page 75 of this issue, was probably much more common in gardens in the early years of the century than it is now, as it is one of those south African bulbous plants which were once the delight of English gardeners, but now are well-nigh forgotten by the present generation of plant-lovers.

Gladiolus tristis concolor is one of the group of species distinguished by the oblong spatulate and acute segments of the flower and by long narrow leaves so strongly ribbed that a cross-section of one of them has the form of a cross. This variety only differs from the typical plant in the absence of spots from the pale yellow flowers, which are marked down the middle with a narrow band of rather deeper yellow. The flowers, which are nearly two inches across the expanded segments, are produced in loose, elongated, two to three flowered panicles, enclosed at the base by the dark green leaves, and, although nearly scentless during the day, exhale a delicate, fragrant perfume in the evening.

The plant from which Mr. Faxon has made the drawing, which is reproduced in our illustration, was raised from a corm sent to us by Mrs. Elwood Cooper, of Santa Barbara, California, in whose delightful garden this *Gladiolus* is well established, flowering there profusely in the open ground in the early spring months. It was potted at the end of September and placed in a cool greenhouse, where it pro-

does well in rich loam, and in winter requires a position where it can get plenty of light in a greenhouse where the temperature ranges between forty and forty-five. It can be grown from cuttings, which root very easily if given a little bottom-heat and shaded from bright sunlight.

Fig. 10.—*Gladiolus tristis concolor*.—See page 74.

IRIS RETICULATA KRELAGEI.—Bulbs of this Iris, which were set out last autumn, will now be in bloom in a cool and sunny greenhouse. Like others of the reticulata group, they will endure more heat than most hardy Irises, and can

be forced into bloom earlier if necessary. The flowers of this plant are a reddish purple, although they vary considerably in shade, and the claw is veined more conspicuously than in the type, and it has a yellow crest. The colors generally are not as attractive as are those of several other varieties of *I. reticulata*. Mr. Michael Barker writes of some of these plants now in bloom at Cornell University, that their leaves are four inches long and the flowers an inch and a half in diameter. Mr. Barker, in his *Handbook of the Irideæ*, says that this variety is the common wild form of the Caucasus, and Professor Foster suggests that it might be regarded as the typical form, since what is known as the true *I. reticulata* is rarely found among imported bulbs, and when crosses are obtained between the type and Krelages variety, the seedlings chiefly follow the characteristics of the latter. Several bulbs are often planted in a single four or five inch pot, but this is an undesirable method, because the bulbs vary greatly in time of their flowering, and there is a remote chance that any three or four would be in bloom at the same time. They should be planted singly in small pots.

Cultural Department.

Cultivating the Persimmon.

In vol. i., page 514, of *GARDEN AND FOREST*, Charles Naudin speaks briefly concerning the improvement of North American fruits, confining his remarks principally to the Papaw, *Asimina triloba*, which he characterizes "the best of the wild indigenous fruits of North America." In a foot-note the editor added the Persimmon, *Diospyros Virginiana*, as being well adapted to cultivation and improvement, and he remarked that "there seems to be no reason why the American Persimmon cannot in time be made to equal the Japanese varieties in size and flavor." But little attention seems to have been given to the subject, however, by fruit-growers, and persimmons still remain among our neglected wild fruits. But we have recently inaugurated a series of experiments in this state, and Illinois has done the same, which have for their object the improvement of these fruits, both of which are indigenous to this state, the Persimmon being especially adapted to the soil and climate of the southern half of each, but it grows to some extent further north. From the latitude of Indianapolis southward it grows luxuriantly without cultivation, but the fruit is generally small. Heretofore suckers have been used almost exclusively in propagating, but these experiments will include budding and grafting the better varieties as well as cross-fertilizing with a view of improving the fruit by increasing the size and reducing the number of seeds and improving its flavor. The work will be done mostly at one of our substations.

In speaking of this fruit at a farmers' institute, Mr. O. M. Hadley said that, although this fruit has been so sadly neglected in the past, it is certainly a fruit that should be better appreciated by all, for it has many desirable qualities. The tree is usually small, but has in some instances been found to reach a height of seventy feet. We rarely find it fruiting north of the forty-second parallel. There are various reasons why it has been hitherto neglected. One is that, in most instances, suckers or seedlings have been used for planting, and these generally die, or, if they live, they produce inferior fruit or prove to be sterile. Another discouraging feature is that it requires a long time for the trees to come into bearing. But, since new modes of propagation and cultivation have been introduced, the persimmon has become a fruit upon which we can rely. Sprouts and seedlings should no longer be used. We might as well rely upon seedling Apples, Pears and Plums as upon seedling Persimmons, for nearly every seed will produce a new variety, differing from the parent fruit in size, shape and quality. In the present method of propagation, seedlings are grown till one or two years old, and they are then budded and grafted. In this way, when one chances to strike an unusually desirable variety, he may reproduce it to a certainty. Then he does not have to wait ten or fifteen years for a tree to begin bearing, for we now have a number of varieties which begin to fruit in from three to five years from the graft. Our best persimmons ripen without frost, contrary to the general opinion that no persimmon is fit to eat until it has been well frozen. There are varieties that ripen in August. The Golden Gem and Early Golden, two of the best, ripen early in September. Many excellent varieties, however, do not ripen until late in October or November, and some even

fail to develop a desirable flavor until midwinter, but this makes them all the more valuable by extending the season. The early-ripening varieties are preferable because of their greater market value, since they present the best appearance, and have often sold for from six to eight dollars per bushel in the large cities. An important point to be considered in selecting a variety is the number of seeds found in each fruit. Most of our old varieties are full of large seeds; but in many of the newer varieties only two or three seeds are found in a single specimen, and some are entirely seedless.

The Persimmon is easily grown when once fairly established, but it requires careful handling at first. When well established we may expect the tree to live and bear an abundance of perfect fruit every year, for neither tree nor fruit is molested by insect or fungi, as are almost all of our other fruits. If one has an old tree which bears inferior fruit it may be top-worked in the same manner as the Apple, Pear and Plum. In this way one may soon transform the worthless tree into one bearing rich, luscious fruit. There are few people who are not fond of sweet, well-ripened persimmons; they are good when eaten from the hand; better with cream and sugar, and they are best of all when made into a pudding, as is done in North Carolina.

Experiment Station, Lafayette, Ind.

J. Troop.

The Grapery.

THE most troublesome insects in the grapery are the mealy bug and the red spider. In houses devoted exclusively to the Vine the first of these pests should never be seen, but since it is often necessary to use Grape-houses for other plants, the mealy bug will sooner or later appear, and once in it is hard to dislodge. This is the best season to attack it. All loose bark must be removed, but it is not necessary to peel the rods entirely, as is sometimes done. Only those pieces of bark which come away easily need to be removed, for these alone are apt to harbor the insects. The kerosene emulsion should be made into a wash for cleaning, not the rods alone, but the rafters, the walls, and, in fact, the entire house. Care should be taken to get it into all the crevices, and this will destroy all active insect-life. The old-fashioned method of painting the rods with a composition of clay, kerosene, sulphur, etc., is unnecessary, as well as unsightly, although it is still preferred by many, and if it is done thoroughly with a stiff brush, so long as the buds are not injured, it will be all the protection that is needed.

As the red spider thrives in a dry atmosphere, water is the chief means of its destruction. It is hard to get rid of during the hot summer, but copious syringing continued for a long time will usually suffice. I have repeatedly syringed Grapes until the berries were coloring, and I once found it necessary to wash off the insects with a syringe before the grapes could be used. Rain-water is the best for syringing purposes, since it contains no lime, which seems to be the cause of the spot when the vines are sprayed. A ripe bunch of grapes can be cleaned without disturbing much of the bloom by holding the syringe over it and giving it a sharp spray in the middle. As soon as the red spider shows itself, which can be easily determined by the reddish tint of the foliage, and the pest rarely appears until after the Vines have flowered, the pipes should be made warm in the evening and painted with lime and sulphur, although care should be taken that they do not get too hot. This treatment must not be resorted to during the flowering period nor after the grapes begin to color. The house should always be kept well damped, except in dull weather. On one occasion I had nearly cleared a grapery of the spider by washing it with hot water. It was an old-fashioned house, and we took the rods outside and thoroughly cleaned the interior, painted the sash-bars and walls with kerosene, and afterward gave them a coating of lime-wash.

There should never be any intermission in the vigilant watch against these insects. Many persons neglect their Vines after the fruit is gone. If it is practicable they should have copious spraying for some time longer and all the air possible. In addition to the remedies mentioned, painting a house is always a great help.

South Lancaster, Mass.

W. Downs.

Preparatory Work.

AT this season much can be done in preparation for the outdoor garden, since many plants can be more readily propagated now than at any other time.

A border of old-fashioned flowers is a pleasing feature in itself in many gardens, and, besides, furnishes flowers suitable for cutting. Among plants for such a border, especially if it is intended to hide an unsightly fence, Hollyhocks

are useful, some of the improved varieties forming massive spikes of brilliantly colored flowers. They can be easily propagated at this time by cuttings. If a few old roots are placed in pots or boxes in a moderate heat a number of shoots will soon be thrown up. These shoots can be taken off when they have made three or four leaves, and rooted in a sand bed. After they have become established they should be placed in a cold frame until planting time.

The garden varieties of Phlox are also particularly effective in such a border. They supply a wide range of color, from pure white to crimson and purple, and in good soil the trusses of flowers are very large. They can be propagated, either by seeds, by cuttings made from the young growth, or by root-cuttings. The best method at this season is to use cuttings made from the young shoots. The stock plants should be treated in the same way as Hollyhocks. Cuttings of Phlox root in a short time if placed in a sand bed in moderate bottom-heat; but it is important that they should not at any time be allowed to wilt, either from want of water or exposure to too much sunshine.

Pentstemons also include a number of showy garden varieties that can be used advantageously with Phlox. Both are useful as cut flowers, and continue to bloom for a considerable length of time.

Among the plants that may be used for edging a mixed border of flowering plants none are more showy than dwarf Nasturtiums. I prefer, in this latitude, at least, to sow the seeds of Nasturtiums in their permanent position out-of-doors as soon as the weather will permit, instead of raising them in pots. The plants whose roots have not been disturbed seem to have more vitality during dry hot weather.

Torenia Fournieri, and its white form, known as White Wings, are also good plants for edging. They produce an immense number of flowers, but are most satisfactory when planted in partial shade. Seeds of these can be had from almost any seedsman, and should be sown as soon as possible to secure strong plants. Torenia-seeds germinate better in the shade than in full sunshine, and should be placed in a warm greenhouse. Canna-seeds should be sown at once; they will germinate much more rapidly in strong heat. The plan of soaking them in warm water for a day or two before planting them is a better way of preparing them for germination than that of filing a hole through the hard outer shell, as has sometimes been suggested. If a succession of Sweet Peas is desired, it is well to start some seeds in pots in the greenhouse. After hardening them off in a cold frame the seedlings may be planted outdoors almost as early as the seeds of the outdoor crop are sown, thus gaining two weeks or more in the time of flowering.

Novelties in Annuals.

FEW romances are more fascinating to one with gardening instincts than a first-rate florist's catalogue, and the fascination seems to increase with one's longer experience. Of course, there is always the familiar list in a seed catalogue, ranging from Abronias to Zinnias, of which we know each item, and most of which have been familiar at one time or another in the garden. But few catalogues are so poverty-stricken as not to offer within their usually vivid covers something which may appeal to the imagination as a possible prize. The more important catalogues always offer, apparently, sterling novelties well worth trial, and if these do not prove equal sometimes to the description, one is at least repaid by the enjoyment of them in anticipation, not to speak of the knowledge gained by experience. Sometimes the catalogue-maker paints his flowers in colors too lustrous, but usually it will be found that the descriptions are correct, as far as they go, although, as is natural, the weak points of a new plant are not insisted on.

As garden plans are now being made and selections for the coming seasons are in mind, a few remarks about the recent offerings of new seeds and plants may be helpful. These notes will be confined to plants and seeds easily secured and to those things likely to interest the amateur grower of a general collection of annuals, etc. A general review of the catalogues reveals an unusually small number of novelties in the more important annuals. No season ever passes without bringing forward some new China Aster, and this year one is offered of distinct form and striking character. This, which is known as "Japonaise," and offered by Vilmorin & Co. in rose and pink, is figured as a large flower, with long, very narrow-pointed, rather irregular petals, and much resembling a Chrysanthemum in effect. Of the recent China Aster the Branching or Candelabra Aster have proved valuable for their late-flowering and long-stemmed habits.

August-flowering China Aster have been much ravaged here lately by the blister-beetle, which devours the flowers as rapidly as they show color. The Yellow Aster should be rather highly colored. The strain of flowers offered this season is said to be of a clear sulphur-yellow. Aster of this color are offered at regular intervals, but previous introductions have always needed the eye of faith to discover the tint. This is an attractive novelty, but it may be said that the sulphur-yellow of the florist usually proves to be a lurid yellow, very ineffective and unpleasing. There are others—The Lady in White, etc.—but few of the annual introductions of Aster prove to be improvements on the standard old varieties, which cost only a trifle, and whose colors are pure and forms entirely satisfactory.

A Wallflower is offered which is said to flower in three months from seed, with the quaint coloring and delightful fragrance of the old favorite, of which we never have too many in the garden.

Sweet Peas have become so important, and are in such demand, that we have the usual number of new varieties, the most important of which seems to be Blanche Burpee, a white-seeded white variety, said to be of very pure color and fine form. This is an Eckford variety. Reports of trials by growers do not indicate that it is superior in purity of color to Emily Henderson, though of slightly different form. California, in recent years, has become the nursery for Sweet Peas, for nowhere else does stock increase so rapidly. In consequence we are now able to secure quickly all the new varieties at moderate prices, and no longer have to wait some years, as we once did, while stock was being worked up in less genial climates. Growers of Sweet Peas have noticed lately that there has been a tendency to produce double flowers among the modern improved varieties, and this year we are offered for the first time seeds of double Sweet Peas, said to produce fifty per cent. of double flowers. This will interest some growers and irritate some purists. To me the double flowers seem to be neither more or less beautiful than the single ones. If one has a greenhouse or warm frame, seeds of Sweet Peas may now be sown singly in thumb-pots with large drainage holes. They readily germinate, and if the pots are set on loose earth the roots will work into it, and it will not be necessary to repot. The plants will be in good condition to transplant as soon as the garden can be worked. This inside planting is particularly useful for the white-seeded varieties and where the garden is too cold and wet to permit of early planting.

Without prejudice I should say that double-flowered Morning Glories, *Ipomoea purpurea*, seeds of which are offered, are curious, not pretty. Those which I have tried have produced a moderate number of flowers with numerous confused petals among a wealth of foliage. The flowers, unlike other *Ipomoeas*, are rather lasting. There are many *Ipomoeas* offered this year, and one can seldom go amiss on Morning Glories, with their usually pure colors. Every one should grow the variety or species which has lately been reintroduced as the "Heavenly Blue," the true *Ipomoea rubro-caerulea*, a most striking and delightful flower.

Those who fancy double Petunias are likely to be very much pleased with the "Double Giants of California," as they possess all the merits of the ordinary double flowers in an enhanced degree, being as large as Hollyhocks. Single Petunias, which have their uses in the garden, have also been transformed in California, and the new strains are now well fringed and as big as any one could desire.

Of other important seeds not new, but still in the novelty lists, *Nemesia strumosa* is a Cape annual with very attractive flowers, which seems to have been little grown yet. The seeds are somewhat like those of Stocks and easily ruined in the seed-pan by overwatering or too much warmth.

Begonia Vernon has proved to be such a good bedding plant that other forms of Begonias for the garden are likely to excite interest. *B. Erfordiae* is said to be a cross between *B. Schmidii*, a well known free-flowering kind, and *B. Vernon*, which is a form of *B. semperflorens*.

Hibiscus Sunset, a tender perennial said to flower the first season, seems to have attractions and to be worth trial. The flowers are creamy, with a crimson maroon centre. A form of same character tried by me last season grew very vigorously.

The other offerings of the season are of minor interest, being mostly new varieties of less important flowers. I notice a new strain of climbing Nasturtiums, called *Madame Gunter hybrids*, but my experience with these has been that they are very vigorous and bright-colored, but no more so than the strains usually offered by our best seedsmen.

Saintpaulia ionantha of last year, still in the novelty list, is a charming little African gesneriaceous plant, which is, of course, to be grown under glass. It is a quaint little plant, forming a rosette of attractive leaves, crowned with small purple single flowers and producing a pretty effect.

Elizabeth, N. J.

J. N. Gerard.

Notes from the Harvard Botanic Gardens.

BRUNFELSIA (FRANCISCEA) LATIFOLIA is a handsome and very satisfactory stove shrub. It makes a shapely plant three to four feet high and produces an abundance of lavender-colored flowers about this time of year. Its leaves are broad, elliptic and acute, four to six inches long and about two inches broad. The deliciously fragrant salver-shaped flowers are produced at the ends of the branches. Of a lavender color when they first open, they become almost white in a day or two. *B. latifolia* is a native of Brazil, and was brought from that country in 1840. Another good species, also in bloom now, is *B. eximia*. Its habit is like that of *B. latifolia*, but the leaves are different, being dark green and oblong-lanceolate, and the flowers are of a deep purple color. This plant also came from Brazil, but was introduced a few years later than the first-named species. When the blooming season is past, the plants should be potted, using a light, rich compost, and they should be grown in a strong moist heat. The Brunfelsias are propagated from cuttings, which root easily if placed in sand with good bottom-heat. The small young plants flower freely as well as the large ones.

The genus *Grevillea* contains plants which bear handsome flowers as well as decorative foliage. Perhaps the most desirable species grown for its flowers is *G. Thelmanniana*, also known in gardens under the specific name *Preissii*. A good specimen, four feet high and a yard across, is almost a constant bloomer here, but at this season it produces its flowers in greatest profusion. It is an erect, much-branched shrub, and the branchlets have a graceful drooping habit. Its leaves are pinnate, and the singularly shaped flowers are bright deep red, and yellow at the tip, borne in dense pendulous racemes three to four inches long. It is a south-west Australian plant, and grows well in a temperature ranging from forty-five to fifty degrees. When it requires potting, this should be done after the flowering season. The pot should be well filled with roots before the plants are shifted into a larger size, and they should not be given too large a shift, since the plant does best in a moderate quantity of soil, when it is less liable to suffer from overwatering. During the summer the plants should be plunged outside in a shady place and taken back to the greenhouse before frost in the fall. Half-ripened wood makes good cuttings, and these root easily in the bench with a little bottom-heat. When the plants are young they require frequent pinching, so as to make them close and bushy.

Botanic Garden, Harvard University.

Robert Cameron.

Damping Off.—At this season there is a great deal of this trouble among seedlings of all kinds, caused by various kinds of fungi. Where small quantities of choice seeds are grown in variety the seeds of each kind are generally planted separately in small pots or boxes, and it is, therefore, much easier to treat them than it would be to deal with a large quantity of seed in a bed or bench. In any case, the soil must be kept as dry as possible, without hindering the process of germination and growth, until the seedlings have made two or three rough leaves. Then they may be safely transplanted, although much watchfulness is still necessary. Where the soil is used in small parcels it may be sterilized in a hot-air oven. This process will destroy the germs of fungi. Sulphur may be mixed with the soil, using one part to thirty parts of soil. Powdered charcoal is also helpful when mixed with soil in the ratio of one to ten. As all propagators well know, this damping off is not confined to seedlings, but also attacks cuttings. It is for this reason that we prefer to use coarse, sharp, clean sand in our propagating-benches, the material least favorable to the growth or retention of noxious germs. But even sand becomes corrupt from long-continued use, and should be washed and sterilized occasionally.

Cornell University.

Michael Barker.

Strobilanthes isophyllus and *S. anisophyllus* are both good plants, and are blooming very freely just now. If they receive anything like favorable treatment they will bloom for two or three months. They are dwarf and bushy, with very dark green leaves, and carry a great profusion of lavender mauve-colored flowers. Young plants are very easily raised from cuttings, and during summer they should be planted out in the

garden, and taken up and housed in the fall when there is danger of frost.

Peristrophe speciosa.—This old favorite is very easy to grow, and brightens up the warm greenhouse during the dullest part of winter. It makes a thick, bushy, but somewhat upright, plant, and its bright purple blossoms are very attractive. Its flowers are not good for cutting, but a group of the plants serves to make a fine display at this time.

Robert Cameron.

Correspondence.

California Orange Groves.

To the Editor of GARDEN AND FOREST:

Sir,—The January freeze in Florida, which so severely injured the Orange-trees, has shown that orange-growing in that state is a precarious business. It is, perhaps, not generally known, but is none the less true, that the orange growers of California are exposed to the same risks that have this year resulted so disastrously to their Florida rivals. During the past four years many oranges have been frozen in southern California, in some sections from twenty to sixty per cent. of the crop having been lost each season. Every year the thermometer has hovered, for a few hours, on a few nights, at a point below the freezing-mark. A temperature of twenty-four degrees above zero for three or four hours means death to the crop. Should it be a few degrees lower, the trees as well as the fruit would be injured. This is a contingency that hangs over the grower every year, and adds greatly to the hazards of the business.

In addition to the danger of frost, the California grower must contend with high freight charges, on account of his distance from market, and with the constantly increasing competition of his own neighbors and of growers in other localities, such as Arizona, where the industry is yet undeveloped, but which may possibly become an active rival in the future. For several years he also ran the risk of robbery by dishonest middlemen. This last risk has been reduced to a minimum by the formation of fruit exchanges, which sell all the fruit of certain localities, ship only to known dealers, and demand a certain stated price, delivered on the train, before the oranges are forwarded. Furthermore, the California grower must make a market for his fruit in the large cities of the east. The taste of consumers must be educated to appreciate the California Navel orange, since most people prefer the sweeter Indian River orange. But California experts claim that connoisseurs and gourmets appreciate more highly the subacid, nutty flavor of the Washington Navel, and that they reject the Florida oranges as too sweet, and, therefore, insipid. If this assertion is true, it is also true that the tastes of the multitude have not yet been highly educated. This is partly the fault of an injudicious handling of the product. Just as California wines are adulterated and initiated to the detriment of the genuine, so the sale of the genuine California Navel orange has been hindered by dishonest growers and dealers, who have shipped unripe, inferior fruit, and sold it as the best. This year, owing to the unexpected demand following the Florida freeze, not a little of this fruit was sent to market before it was at its prime. An additional reason for haste was the fear of a freeze in California.

The estimated crop in California is two and a half million boxes, about half the amount of the Florida crop, had there been no frost in that state. At the start the net price to the grower, for the best Navels, was two dollars a box. California growers anticipate that the frost in Florida will check orange-growing in that state for several years to come and so give their own product a better chance than heretofore to gain favor in eastern markets.

Very few new Orange orchards are being planted in California, as compared with the plantings of former years, but the price of the best orange land has not been materially reduced. The best orchards now in bearing cost their owners fully one thousand dollars an acre before returns are received from the investment. Except in isolated instances, good orchards are not being sold, unless at figures based upon that cost to the holders. Tourists who have expected to secure bargains on account of the general depression in business have, as a rule, been disappointed. The conditions of the present year, unless the California fruit should also be frozen, will encourage owners to maintain fancy prices.

It is an open question whether these orchards are worth fancy prices. Their owners no longer hold out to intending buyers the profuse promises of boom days, but claim only that these orchards will pay a good return for labor and for the

capital invested. A moderate estimate of an average yield from a good, well-cared-for, mature orchard of Washington Navels is three boxes to the tree, or from two hundred and forty to two hundred and seventy boxes to the acre. This would seem to offer satisfactory returns, even at one dollar a box, net. But, on the other hand, taxes, labor and freight rates are all high. In some places the water-supply is uncertain, and the orange-growing communities, like all communities which depend for prosperity upon one resource, are liable to complete ruin from a single cause. This danger may be remote, but its existence, however remote, is a constant menace. Such ruin was formerly threatened the Orange groves by their parasite pests. These have been largely subdued, although the scale insects, particularly the red scale, are still troublesome. There remains that insidious enemy, frost, against which no vigilance can guard, and which is as voracious as fire. Although no frost has yet been severe enough to injure the trees in California, it is not impossible that Florida's experience this year may be that of California next year. Altogether, an Orange grove seems to be very like a mine—an excellent thing when producing, but liable to a disappointing pinching of the vein.

Wm. F. Tisdale.

Redlands, Calif.

A Venturesome Hepatica.

To the Editor of GARDEN AND FOREST:

Sir,—Several years ago I began to carry home with me from walks in fields and woodlands the roots of wild plants and set them in a suitable part of the garden. Many of these are still thriving, though some, like the Trailing Arbutus and Fringed Gentian, have resented the change and died out. Foam-flowers, Tiarella, from the Catskills, are well established here, and Harebells from the Adirondacks, Cardinal Flowers from Long Island, Blood-root from Staten Island, and a wide range of wild flowers from other near-by places. Besides the flowers provided in season, these wild plants afford occasional surprises, as when on the 26th of December last I found under a winter covering of leaves in a clump of Hepaticas, brought from Staten Island seven years ago, a sturdy flower which did not seem to know that it was braving the cold of the shortest days of the year. A few days before a Blood-root ventured to unfold its white petals, and on January 11th of this year, when for a few hours spring seemed in the air, two more Hepatica flowers ventured out. There were buds which promised to open soon, and, no doubt, they are awaiting the melting of the snow and will expand with the first genial weather. The place where these flowers appeared is sheltered from the west winds and from the east, but fully exposed to the north and south. Shall we call them belated autumn flowers or precocious harbingers of spring?

Bayonne, N.J.

H. J. S.

A Search for Gold Thread.

To the Editor of GARDEN AND FOREST:

Sir,—It is now almost a year since inquiries in a local newspaper as to where several plants, among them Gold Thread, Coptis trifolia, and Wild Ginger might be found, led to the formation of a society bearing the rather ambitious title of the "Natural Science Association of Harrisburg." Although the society numbers among its members an ornithologist of distinction, and several amateur students of entomology and geology, its chief interest has been from the beginning botanical. The club meetings are held once a month, when plants are brought in for examination and exchange, or papers are read and discussed. When the weather permits, weekly walks are taken to or from points within a ten-mile radius of Harrisburg. These walks, or explorations rather, as they are generally across country, some of it very rough, are a revelation to many of the members of the inexhaustible supply of subjects for investigation close to a city.

Out of a population of fifty thousand people, it is doubtful if a hundred know of the existence of the Iris meadows on the Conodoguinet; of the Rose Mallows in the swamp running from Harrisburg to the foothills of the North Mountain, five miles distant; of the Hepatica-covered bluffs on the eastern side of the swamp, or of the great belt of Red-bud that lies at the edge of the woods on the mountain itself. Gold Thread is yet to be found, but we know now where to look for Wild Ginger in the ravines of the York hills, the blue bells of the Mertensia Virginica in the meadows at their base, and the one meadow lying in a fold of the hills where Castilleja coccinea is found.

Another plant, so far found in only one place, is Lithospermum canescens, on a limestone bluff overhanging the Swatara Creek. Quantities of herbaceous plants have been located

and the time of their flowering noted as a guide for the future; among these are the great beds of *Trillium grandiflorum* on the Second Mountain. In Franklin County, a search for Gold Thread in the Rhododendron swamps of the South Mountain revealed *Dalibarda repens* and *Waldesteinia fragarioides*. In the same swamps are found *Magnolia glauca*, Sweet Magnolia it is called there, and quantities of fragrant Azalea, *R. viscosum*, also var. *glaucum*, but thus far no Gold Thread. The meadows of that county show quantities of *Gerardia tenuifolia*, and in one meadow *Pycnanthemum linifolium* and *Poterium Canadense* were found. The finding of *Magnolia glauca* was of special interest, since Professor Porter assigns its western limit in Pennsylvania to a ridge of the South Mountain, in Lebanon County, or quite seventy miles farther to the east.

All the South Mountain plants were located at an elevation of about one thousand feet, but as none of these last mentioned have been found near Harrisburg, it is a question whether the cultivation of limestone soils destroys many of our most beautiful wild flowers, or whether, like the Rhododendron, many of them are never found in limestone soils.

Harrisburg, Pa.

M. L. D.

Meetings of Societies.

Western New York Horticultural Society.—IV.

THE brief notes which follow conclude our report of the late annual meeting of this society:

INSECTS INJURIOUS TO FRUITS.

Professor M. V. Slingerland referred to the introduction of the San José scale, and then of the similar Plum scale, which has done much damage in some fine orchards in western New York. These remain on the tree all the year as hard, brown, conspicuous scales, easily found, and appearing like hard brown peas, which leave white spots under them when removed. The eggs are laid under the scales about the last of May, the scales usually being on the under side of the branches of the last two years' growth. The only alarming appearances have been, so far, confined to Geneva, Rochester and Lockport, but they caused considerable damage. The indications are, the young scales on the trees, which may be found in July, the old cases on the trees, and the presence of large quantities of honey-dew and its black fungus, as in the case of the Pear-tree psylla. The young scales pump out the sap and thus stunt the growth. There is a similar insect on Quinces, Apples and Elms. The Japanese Plums do not seem yet to have been attacked. In August the young scales place themselves and never move again. The next May egg-laying begins about the middle of May and continues till the hard case is nearly full, each mother laying about a thousand eggs. The eggs begin to hatch about the first of July, and the young then begin to crawl to the leaves, where they place themselves near the veins, preferably on the under side. The scales, now five millimeters long, cannot readily be distinguished without a lens. About the last of August they migrate to the under sides of the smaller branches, where they pile up often two or three layers deep. They are brown in August and seal-brown later. About ten per cent. fall with the leaves. The scales are now about twice as large as when hatched. The next spring they are full-grown. If left to themselves they would move slowly, but in their migrations they may get on birds, insects and leaves and be thus transferred. There is little danger of infection from nursery stock, as the scales have not been found on trees under five years old. The scale has two enemies—one a lady-beetle that eats it, and a parasitic insect. The scale must be killed by contact. The kerosene emulsion of a strength of one to four will kill the greater part of them. Between May and October there is but one week in which to operate with any chance of success, and that is about the first of July, when the insects are moving on the limbs. It is impracticable to kill them on the leaves, except by gas treatment, and this is too expensive. In the autumn, after the leaves fall, the emulsion diluted to a strength of one to four should be used and the tree drenched with it. The dead scales are a bright brown, hard to distinguish from the living ones. Most of the scales are on the under side of the branch and in crevices of the bark. If sprayed in the fall, again some time in the winter, and in March twice, the cost will be about three cents a tree for a thorough application.

PEAR BLIGHT.

In an illustrated lecture on this subject, Professor Waite showed that the flowers could be infected artificially, the nec-

tary being the only part of the tree that can be successfully infected without puncturing. It was shown, experimentally, that insects carry the germs in their rounds from flower to flower and thus inoculate the blossoms. Trees overstimulated, especially with nitrogen, seem to take the blight most readily. The blight works downward, and the point it has reached at any time is clearly defined. If the diseased parts are removed the roots recover. In cutting off blighted portions in the dormant season it is only necessary to cut just below the blight. In the growing season the branch must be cut a considerable distance below, and in both cases it is advisable to burn the parts.

The germ usually enters the tips next the blossoms, and advances towards the trunk. Three weeks after the twigs die the germs usually all die. The germs have never yet been found in the soil, but they have been found to live over in affected parts next to the living tissues. They will sometimes live through Bordeaux mixture. If the weather could be controlled, then pear-blight could be, as moist, muggy weather favors it. Bartlett is one of the worst varieties to blight, and so is Clapp's Favorite. All Pear-trees, whether dwarf or standard, should be headed in as a preventive measure. Nitrogenous manures should be used sparingly, and blight-proof varieties, such as Angoulême, Keiffer and Lawrence, should be preferred.

Mr. Beach said there had been some injury this year from spraying with the Bordeaux mixture. If the copper sulphate is diluted, or partially diluted, before adding the lime, and the whole is then well stirred before adding the ferrocyanide there will be no trouble if no brown color appears. Free copper is often the cause of injury. The extra irritation of the cold damp weather makes the roughness on so many varieties, Western Beauty and Ben Davis among others. Apples that have been sprayed, even in a wet season, keep better than others. He also said that lime was fresh-slaked if it had been kept under water constantly after it was first slaked and not allowed to dry. He cautioned users of the Bordeaux mixture to turn the nozzle back in the barrel after every stop of even a minute, as the ingredients settle immediately, so that the first application will otherwise be too strong.

Mr. Woodward spoke encouragingly of nut-culture. He had Paragon and Numbo Chestnuts six years old that have borne three years. He took cions in 1893, and top-grafted on native trees, and had fruit in 1894. Paragon is four times as large as our common chestnut. It is a native seedling of a foreign variety. Numbo is larger than Paragon, but not so sweet. He whip-grafted, cleft-grafted and slipped cions under slit bark. His greatest trouble is in having the cions broken off by wind after they begin to grow.

Among the new diseases reported are the Peach-scab and the powdery mildew of the Peach. In Niagara County, Bordeaux mixture injured the foliage, but did not check the trouble. Ammoniacal carbonate of copper also hurt the foliage, with but slight results in checking the disease. In Tompkins County there was a new Raspberry disease, in which the fruit dries on the bushes, the stems are brittle and break like pipe-stems.

Mr. Hooker said he had three to five hundred trees, fifteen years old, killed outright by the scales. In his neighborhood they had been found on Hickory, Elm, Orange, Quince and Honey Locust. The German Prunes are not exempt, but the Lombard and Reine Claude were the worst affected.

Notes.

In our notes on new plants last week it should have been stated that all the hybrid Cypripediums named were raised at the United States Nurseries of Messrs. Pitcher & Manda, at Short Hills, New Jersey.

Dr. Hoskins says that the Green Mountain grape ripens in northern Vermont thoroughly every year, and in thrift, productiveness and quality is proving all that could be desired as a family grape; and he adds that there is only one other grape of good dessert quality which he has found early enough for this region. Is this the Diamond?

One of the most famous trees in Germany, the so-called Cathedral Linden of Brunswick, fell and perished a few months since. It must have been large enough to be popularly noted five centuries ago, for in a pamphlet published in the year when America was discovered may be read the statement that, in 1473, the summer had come so early that "the Lime-tree of Brunswick" was in leaf on Easter Day.

We have received from Messrs. Siebrecht & Wadley several flowers of the Rose Belle Siebrecht, which has already been described in these columns. We only need to add that careful observation of these flowers proves the truth of what has been claimed as to their lasting qualities and as to the singular purity of their color under artificial light.

Experiments at the station in Kingston, Rhode Island, confirm former tests and show conclusively that air-slacked lime tends to increase the disease known as the scab of potatoes. The natural acidity of soils tends to diminish the disease, and the reason why barnyard-manure aggravates it is attributed to its alkaline action in overcoming the souring of the soil. Barnyard-manure, where stock is fed on uncooked potatoes or beets which have the disease, may carry the germs to the soil and increase the disease.

A correspondent of the *Baltimore Cactus Journal* advises that when Cacti are repotted, the most suitable time for this being February or March, the soil used should neither be damp nor dust-dry, but it is best to err on the dry side. When turned out of their pots most of the soil should be shaken from the roots of the plants, and the roots should be well spread out when they are shifted, and good drainage should certainly be secured. A handful of sand put directly under the plant is in all cases beneficial.

At this time of the year branches of spring-flowering shrubs and trees, when placed in water, readily open their buds, and in one of the up-town flower-stores, where a specialty is made of this kind of decoration, among the plants treated in this way were Crab-apple, Japan Quince and Forsythia. Flowering sprays of different species of Acacia, Chorozema and Jessamine are also occasionally seen, and among potted shrubs in bloom now are Cytisus, Azaleas, Ericas and double-flowering Almonds. Among the commonest herbaceous potted plants in flower and on sale are Cinerarias, Pansies, Primulas and Cyclamens. Cut flowers of white camellias, which have been practically banished for a long time from the markets, seem to be slowly gaining a foothold. Of course, there are quantities of hyacinths, tulips and daffodils, with poet's narcissus, which seem to be popular for button-hole bouquets. Cattleyas are very abundant, and retail readily at fifty cents each.

Unless Strawberry-plants are shipped very early in the season, there is much danger that they will heat in transit. This is especially true when they carry a considerable quantity of heavy green foliage, which has probably been warmed up in the middle of the day before the plants are packed, and packed closely, as is often necessary. Mr. J. H. Hale writes to the *Florists' Exchange* that specialists in Strawberry-plants put on large numbers of men to dig them early in the morning, and carry them at once into cool cellars, where they are trimmed and packed. But even where no digging is done in the middle of the day, unless they are very carefully handled, the plants are in danger, and, therefore, an experiment now in progress in Delaware will be watched with interest. A nursery firm there has built a cold-storage house, in which all the Strawberry-plants are put as fast as they are packed, and cooled through before they are delivered to the transportation companies. The expectation is that with this treatment there will be no trouble from the heating of the plants.

Mr. John N. May writes to the *American Florist* that because Roses are coarse and gross feeders many persons make a mistake in giving them, when grown under glass, too much, or, at least, too strong liquid-fertilizer. It is never safe to use more than half a pound of nitrate of soda, for example, to fifty gallons of water, and an application of this once in twenty-five days is often enough. Old plants, which have been growing two or three years in the same soil until it is a mass of roots, will take liquid-manures oftener, especially when the days are getting longer, the sun brighter and the vital forces of the plant more active. The safest method, however, is to feed lightly; that is, to make the liquid fifty per cent. weaker than is usually considered the proper proportion, and when the plants are in proper condition for being watered to give them a good soaking with this diluted food. The roots can then take it up at once and the plants will feel the effect immediately. Liquid-manures of all kinds should be used with great discretion, and Mr. May never applies any liquid which is so much discolored that he cannot see through it.

Small quantities of lettuce which have escaped the frost in Florida are now in market, but, except that which is grown under glass, most of it now here comes from Bermuda. A few new potatoes are also coming from Florida, but the supplies of fresh vegetables from our southern seaboard has practi-

cally stopped for the present. Such hardy plants as Strawberries will, no doubt, put out new blossoms and bear a crop of fruit later on, but there never has been in this country so great a destruction of garden crops by frost as that caused by the recent cold weather in our southern states. All the string beans we have are now coming from Bermuda, and Havana is sending us tomatoes, peppers, okra, eggplants and onions. It has been a rich harvest for those who have grown vegetables under glass. The market has readily taken at good prices all that has been offered. Long, slender green shoots of forced asparagus sell for \$1.50 a bunch of a dozen stalks. Cucumbers bring twenty cents each, lettuce fifteen cents a head, new carrots ten cents a bunch, ordinary red tomatoes seventy-five cents a pound, and a fancy yellow variety which comes in small quantities from Hackensack commands \$1.00 a pound.

A bulletin just issued from the United States Department of Agriculture gives a concise description and history of the Peanut, together with notes on its cultivation and uses. As is well known, this is not really a nut, but, more properly, a ground pea. Analysis gives the peanut a high rank as to its food value, since it contains twenty-nine per cent. of protein and forty-nine per cent. of fat, and it should be classed with such concentrated foods as the soja-bean and cotton-seed, while the vines are superior to Timothy hay as feeding stuff, and, of course, would be equal, or superior, to Clover hay if any considerable percentage of nuts were left on the vines. The average yield of peanuts in Virginia is about twenty bushels to the acre, and, in Tennessee, thirty-two bushels, but fifty to sixty bushels ought to be an average crop, and one hundred bushels not an uncommon yield. Fair Peanut-land, when properly treated, should produce fifty bushels to the acre, with one or two tons of excellent hay, in ordinary seasons. Four million bushels are annually raised in this country, which is only about one-seventh of the crop of the world. Millions of bushels are used in the Old World for the production of oil, in which these nuts are very rich.

No more beautiful flower grows in New England than the Sabbatia, and at Plymouth, where it is especially profuse and luxuriant on the borders of the ponds so characteristic of that part of eastern Massachusetts, it is held in peculiar affection, and, one may almost say, reverence. It is locally called "the Rose of Plymouth," and during its brief season of bloom is sold in quantities in the streets of the town and used in the adornment of houses and churches. Its name comes from that of an early Italian botanist, Liberatus Sabbatia; but this well-established truth is totally disregarded by local tradition. Almost every one in Plymouth firmly believes that the title is due to the fact that the Pilgrims of 1620 first saw the flower on a Sabbath-day, and, entranced by its masses of pinkish lilac-color, named it for the holy day. Indeed, this belief is so deeply ingrained in the Plymouth mind that, we are told, strong objections are made if any other flowers are irreverently mingled with it in church decoration. Yet the legend was invented not more than twenty-five years ago by a man whose identity is still well remembered; and thus it is of even more recent origin than the one, still more universally credited, which says that the Pilgrim Fathers landed upon Plymouth Rock.

Large areas of Pine-lands in lower Michigan, from which the timber has been cut, have passed back to the control of the state on account of the non-payment of taxes. The purchasers have thought that this sandy soil, especially where it has been burned over, will not produce a second growth of Pine for a long time, and it is, therefore, abandoned as a perpetual wilderness of deciduous coppice-wood, valueless for timber. The editor of the *Northwestern Lumberman* quotes the opinion of Mr. Carey, special agent of the Forestry Division of the Department of Agriculture, who has been making investigations throughout the state, and he has arrived at the conclusion that this land can again produce as fine a growth of White and Red Pine as ever grew on this continent. All that is necessary, he says, is to keep out fires, browsing sheep and cattle, and in forty years the second growth of Pine will make profitable cuttings, as it has done in Maine, New Hampshire and other parts of New England. It will be a fortunate thing for Michigan if this hopeful view proves correct. In any case, it is worth while for the state to take these lands in hand, and begin at once not only to pass laws for protecting their young timber-growth, but to enforce these laws with vigor. We should expect to find that lands which have been burned over and over again have lost much of their original timber-producing power. But this is a good reason for husbanding all the fertility that remains.

The Defacement of Scenery.

ABOUT a month ago a bill was introduced into the Massachusetts House of Representatives entitled "An Act to prevent the offensive use of buildings for advertising purposes." This act makes it unlawful to paint on any house, barn or other building any advertisement of a patent medicine or other commodity in letters or characters which are more than six inches long and four inches wide, and the violation of this statute is to be punished by a fine not to exceed \$500. We hardly understand why obtrusive vulgarity of this sort is more offensive when it is painted on a shed or a mill than when it is displayed on the spacious and ugly board structures which are usually braced up in the most conspicuous parts of the landscape. And certainly natural objects need some protection against this vandalism, for every one has had his feelings outraged when he has seen in different parts of the country rocks and cliffs covered over with highly colored importunities to use one man's ready-made soup or to try another man's remedy for indigestion. Two or three years ago the newspapers were filled with protests because the face of Storm King, on the Hudson, had been desecrated by such an advertisement, and the correspondence on this subject brought out the fact, which did not seem to be generally known, that laws in New York state already existed which made such wanton defacement of scenery a misdemeanor to be punished by fine or imprisonment. The prosecutions under these laws have certainly been very few, and no one has ever been sent to prison for violating them.

Americans are not the only sinners in this respect. It will be remembered that no longer ago than last year the Prime Minister of Great Britain spoke bitterly of the way in which the beauty of the rural and seaside scenery of England was disfigured by this advertising plague. Lord Rosebery said that the people had become so used to seeing the picturesque and historic beauty of the old towns marred by the paint-pot that they had ceased to utter any protest, but now when the advertiser had covered over all the station walls and gable-ends of town buildings, and was spreading himself over the woods and fields of the country, it was time that steps should be taken by Parliament to put a stop to the destruction. But acts of Parlia-

ment will do little more good in England than will laws in the state of New York or in Massachusetts, unless there is a public opinion behind them which secures their enforcement. Within the limits of this city, and on lands controlled by the Park Department, massive rocks which constitute the chief beauty of the property have been hopelessly disfigured, and yet no action was ever taken against the offender, although the department had ample power to bring him to punishment. No protest against this defacement was made, so far as we remember, by the press of the city, nor was the department criticised for neglecting to prevent it.

This injury to natural beauty will go on just so long as it is not a generally appreciated truth that natural beauty is to a certain extent an inheritance of all the people, that it has a real value like pure air and fresh water, and that the man who destroys it, therefore, violates as distinctly the rights of the public as one does who fills the air with noxious vapors or pollutes the sources of public water supply. Great corporations who build railroads, sink oil wells and open mines and quarries never inquire about the wounds they inflict on the face of nature, and no one protests against the desolation which they make, partly because we consider this one of the sacrifices we are called to make on the altar of material progress, and partly because few people recognize the fact that landscape beauty is anything like a vital necessity to the mental and spiritual health of a people.

The plain truth is, that natural beauty has an intrinsic value as a refreshment to the spirit, and a restorer of the health of mind and body. It is practically and actually effective in making such appeal to the imagination that as we contemplate it we are elevated for the time above the wear and weariness of every-day life into an atmosphere of restoration and repose—into a realm of higher and serener thoughts which bring health to the body through their tranquilizing influence on the spirit. In short, the contact with natural beauty is one of the potent agencies for establishing sound minds in sound bodies; and since this is the source and condition of all well-directed ambition and effort, a reckless destruction of this beauty is a blow not only at one of the highest and most satisfying pleasures of the people, but at the public health and the public wealth.

This is not a merely sentimental or fanciful view of the case. It is fundamental truth. When Lowell writes that "the landscape, forever consoling and kind, pours her wine and her oil on the smarts of the mind," when Wordsworth asserts that the presence of nature "disturbs him with the joy of elevated thoughts," and whenever, in the highest poetry, the elementary and controlling feelings of the soul find expression, this profound truth is recognized. No enlightened man disputes it. Why, then, should it not be accepted as sound doctrine that it is one of the inalienable rights of man to enjoy the unimpaired beauty of the world into which he has been born, and that it is the duty of society which has inherited this beauty to transmit it unimpaired to posterity? We may be assured in the first place that this is no transient sentiment which will pass out of fashion. The imagery of the Old Testament and the earliest poetry of the world prove that these same emotions swayed the races who laid the foundations of our modern civilization. Susceptibility to the influence of natural beauty is one of the original and essential qualities of the human mind, and it is never likely to be outgrown. Indeed, we may be sure that the beauty of the outward world which is preserved for posterity will be more highly appreciated by them than it is by us, for this feeling has grown in depth and strength with the growth of the race, and it will probably continue to grow.

Taking this view of the case, statutes leveled against the irreverent use of paint in the landscape seem to be an altogether inadequate expression of what ought to be the prevailing thought and habit among cultivated people. It is to be hoped, of course, that the Massachusetts Legislature

will enact this law, and that other states will enact similar and more stringent ones, but after all, as has been stated before, we not only need a public sentiment, but a public conscience in this respect, which will do more than merely resent the wanton defacement of natural beauty—which will take pains to preserve and develop by reverent treatment scenery which inspires noble thoughts by its sublimity or soothes and refreshes the mind by its beauty. Societies for the protection of such scenery have been established in many European countries, and certainly it is high time that some organization of this kind was formed here. The very existence of such an organization, not to speak of the influence of its publications and of its active efforts at prosecuting offenders, would arouse people to know their rights and to assert them. A few intelligent men are now making protest against stripping the forests from our mountain-tops because this impairs the natural and needed supplies of timber and of water. Why not also protest that the destruction of the woods mars the beauty of the landscape which is our common inheritance? When this subject is properly brought home to the intelligence and moral sense of the people the reckless destruction of natural beauty will not only be held a misdemeanor in law, but it will be considered a gross outrage against common decency, and the man or corporation who heedlessly and needlessly defaces the beauty of the world will be considered a public enemy.

The Care of Urban Parks.

AT one of the meetings of the World's Fair Horticultural Congress in Chicago, Mr. William MacMillan, Superintendent of Parks in Buffalo, New York, read a paper on the improvement and care of public grounds, the concluding paragraphs of which are here reproduced:

In every public ground there should be a due proportion of smooth lawn or open green. There is a special beauty in a broad stretch of fresh-hued greensward, made to be looked at and not trod upon. Park visitors in general think they can "eat their cake and have it too"—enjoy the beauty of a finely kept lawn and yet daily trample the sod. All restrictions are resented, and each green lawn is coveted for games of some sort, to an extent incompatible with its preservation. Where the turf has any shade it is wanted as a "picnic common," with the same result. Margins of walks are obliterated in like manner, and beaten footways trod out wherever any short cut can be found. There is no feature of a park so popular as a short cross-cut, especially if the practice is known to be a trespass. The license first overlooked because no damage is yet apparent, then openly allowed because the usage is so common, soon spreads to like abuses of the shrubbery and younger trees, with results still more destructive. In all large grounds suitable sections are especially prepared for playgrounds and commons, but it is essential that the spaces reserved for smooth lawn and ornamental planting should not be overrun.

Because, as a rule, the damage done by each trespasser is in itself scarcely perceptible, few realize the great destruction, both to greensward and shrubbery, which results from the constant repetition, day after day, of petty trespasses, each in itself insignificant. The worst of it is that as soon as at any point some special line of trespass begins to leave a clear mark behind it, the evidence of the damage done, instead of restraining others, seems rather to tempt every passer-by to repeat the offense. In proportion as the tasteful and ornamental character of the grounds disappears there seems always, of course, the less reason why regard should be given to any stray remnants of the original habit in which it is dressed. Park police are powerless to stop such usages once they get headway. Only those persons can be checked who can appreciate the necessity of strict regulations. Arrest and trial are useless, as the punishment inflicted, if any, is never sufficient to warn others, or even to prevent a repetition of the same offense.

Thus, instead of the neat and trim aspect which a pleasure-ground should exhibit, it assumes a neglected, slovenly appearance, very unsightly to every person who has any regard for the tasteful embellishment of public grounds. Much of the pleasure is lost which would be enjoyed if the grounds were carefully kept and orderly behavior everywhere enforced. The value of the grounds is utterly lost to those visitors who may wish to gratify a refined taste for the beautiful in nature.

Apart from loss of character and reputation, the loss involved in the cost of annual repairs, or by permanent destruction of property, is also an important item.

The care and satisfactory management and maintenance of public grounds is a more difficult work than their construction. The general design of the improvement may be clearly imprinted on the grounds, the controlling motive may be apparent, the beauty beginning to develop be appreciated, and it becomes a popular resort for the recreation it was intended to provide. But many misunderstand its function, take little interest in the natural beauty of the landscape, look upon drives, rides and walks as more important features than the scenery in which they are set, see in the open greens only an opportunity for athletic games, in the woods only a resort for the usual picnic sports, and in the waters only facilities for rowing, sailing or skating, according to the season. So demands are soon made that permission be given to each class to indulge in the outdoor pastimes in which each is especially interested for the time being. Owners of fast horses want a speedway for racing sports, equestrians want the open stretches of turf for galloping on, hurdles to be set up for them to jump over, and a special section reserved for polo playing; bicycle riders want special tracks for greater convenience and for competitions of speed, and visitors on foot want the license of going anywhere at will and doing as they please.

Others spy out a chance to advance some personal scheme of private advantage under the cloak of concern for the public good. Space is wanted for a merry-go-round for the amusement of the children. Some sharp slope is just the right pitch for a toboggan-slide or a coasting-rink. An amphitheatre-like sweep of bank is coveted for spectacular exhibitions, circuses, shooting-matches, etc., with all their paraphernalia of tents and enclosures. The smaller greens must be devoted to tennis and croquet, the larger to baseball and lacrosse, and the largest to military maneuvers and mass-meetings. Thus at every point usages creep in which are in many respects inconsistent with the conservation of natural beauty of the grounds, and in the end utterly destructive of its most attractive features.

Similar damages arise from other causes. The owners or occupiers of the land adjacent to the park boundary become dissatisfied with their position at the back of the picture. They think it would be much improved (to them, at least) if the frame were knocked off. The effect to the public at large, who look at it only in front, is to them a matter of no consequence. So new gateways are urged wherever any plausible plea can be offered for them; openings in the border screen are wanted opposite this man's bay-window or that man's vacant lot, to improve the private view or to help the sale of the property. These schemes succeeding more or less, a combined raid is next made on the boundary fence, because "it is unsightly, it is useless, it is a relic of barbarism, a sign of aristocratic exclusiveness," and so forth. The grounds belong to the public, and they should not even seem to be shut out from their own. If removed, they may be trusted not to abuse the confidence reposed in them. The temptation to trespass would be resisted, and the proper gateways only would be used for entrance or exit just as before. The fence accordingly is removed, the boundary is immediately overrun in every direction, the regular walks are neglected, tracks are at once beaten out in the grass on all the direct lines of passage, and all semblance of order vanishes from the grounds along with the last vestiges of garden ornament and finish.

These usages are fatal to all artistic design, as shabby gentility is especially offensive to good taste. Their effects are more or less visible in all our public grounds, and most seriously deface what were originally the fairest portions. This has led to some reaction against any elaborate finish, and to a demand for simplicity to the extent of crudeness; all open grounds to be treated as commons, and all plantations as if they were natural woods. But the natural beauty of the simplest scenery is soon destroyed by such public usage. Therefore, whatever the style of improvement may be, it must be maintained intact after its kind, else all the money spent on it is worse than thrown away.

This is not meant to discredit the taste which selects for public grounds sites where pronounced natural features are the chief attraction, without any improvement, so-called, except what is necessary for convenient locomotion in public use. Examples of this class may be cited where their grandeur or picturesqueness make fine embellishment an intolerable intrusion. Such are the Wissahickon Glen, at Philadelphia; the gorge of the Genesee, at Rochester; East Rock and West Rock Crags, at New Haven; the Lynn Woods, at Lynn; Burnett Woods, at Cincinnati; the state reservations at Niagara and Minnehaha, and the several national reserves. The taste

which perceives the scenic value of such places and conserves them for public enjoyment, is a promising sign of the strength of public sentiment which in any community may be depended on to support all intelligent effort in the improvement of a public ground to conserve and develop its natural beauty.

The Chestnut in the West.

THE Chestnut has naturally a somewhat restricted range, its western limits being in the states of Michigan, Indiana and Tennessee. It illustrates, as do many other forest-trees, the fallacy of supposing that natural distribution is a reliable indication of possible range under cultivation, for the tree can be successfully grown throughout Missouri, the eastern counties of Kansas and Nebraska, and the southern half, at least, of Iowa. I know splendid trees in bearing at Des Moines and Kansas City, and there are thrifty specimens at Farlington and Manhattan, Kansas. What is even more surprising is that the tree can be seen at Fort Collins and Denver, Colorado, though, through lack of irrigation at the latter place, the thrifty little plot of them has been almost entirely destroyed.

The best Chestnut-trees that I know in the west are in the grounds of Mr. L. A. Goodman, at Westport, a suburb of Kansas City, where they occupy two rows in the orchard. The trees are twenty years old from the seed, were transplanted twice before being set in the orchard, and some of them are now forty-eight feet high, with a spread of branches of twenty-eight feet. There are twenty or more of them, and all are of good form and habit, and as healthy as any trees of this species wherever found. Mr. Goodman has grown them for their nuts, and, being an expert horticulturist, he has developed full crowns and comparatively short trunks, treating them essentially as he has the Apple and Cherry trees which make up the remainder of his orchard.

The Chestnuts at Farlington have been in close mixture with Wild Cherry, Black Walnut, a few Catalpas and Ailanthus, planted four feet apart each way. These were set as yearlings in 1882, and are now fifteen years old. They average twenty-eight feet high and about three inches in diameter, breast-high. The trunks are cleaning themselves well, and are free from live branches to a height of ten or fifteen feet. The close planting has undoubtedly retarded their growth, but it must be remembered that the Farlington trees have received practically no attention in twelve years. The trees in these two plantings fairly illustrate the difference in management for timber and for nuts, and this point cannot be too strongly emphasized. In growing any of the nut-trees—Hickory, Butternut, Pecan, Walnut or Chestnut—if timber is to be the crop, close planting, with a proper regard for light requirement, should be the method pursued. If the nuts are to be the crop, wide spacing, high cultivation, with proper attention to fertilizing the soil and pruning are necessary. In the one case we seek to get length of straight trunk at the expense of crown, and in the other we pay little attention to length of bole, and develop the crown to its fullest proportions.

A good many years ago, Mr. James Smith, the veteran horticulturist of Iowa, planted Chestnuts along his fence rows, and in the early eighties the small boys of Des Moines were surreptitiously enjoying the unique pleasure of opening chestnut burrs.

There is a single Chestnut-tree, fully eighteen inches in diameter at the ground, on the lawn at Professor Popenoe's, Manhattan, Kansas, and several small Chestnuts in the grounds of the Colorado Agricultural College, at Fort Collins, are doing well under irrigation. On the Everett place, near Denver, trees of this species attained a height of twenty feet, when they failed for lack of water. These were planted in a forest-tree nursery, which was afterward abandoned and the water withdrawn.

In growing Chestnuts it is best to plant the seed where the tree is to stand, but if transplanted at one and two years old they can be removed without especial difficulty. The

nuts should either be planted in the fall, or kept in a well-drained place in the open air, in layers a few inches thick, with a covering of leaves and boards. Fall planting is best.

Charles A. Keffer.

Plant Notes.

Spiraea Thunbergii.

THIS Chinese shrub is not only one of the best of Spiræas, but one of the most useful of all hardy shrubs, from the fact that it is attractive from early April till late November. It bears flowers every year, which are small individually, but as they are produced in corymbs on the end of the lateral branches in great profusion they completely cover the shrub in early spring. A habit at once graceful and compact, with slender willow-like leaves of a bright, cheerful green, makes it an interesting plant all summer long. In the autumn it holds its foliage until nearly every other deciduous shrub is bare, and then it turns first to a deep bronze, and afterward to a brilliant orange or scarlet, or sometimes pink, colors which are so effective that the shrub is worth planting for its autumn tints alone. Some complaint is made that the lower portions of the stem of the *Spiraea Thunbergii* become naked and unsightly with age, but this is a fault with many shrubs and one readily overcome by pruning. Its only real drawback in this region is that the very tips of some of its branches are occasionally killed in severe winters, as will be seen in the picture of a flowering branch on page 84.

Mrs. R. Swain Gifford, who sends us some interesting notes on the behavior of this shrub in New Bedford, Massachusetts, says that "in landscape-gardening its delicate and graceful habit makes it one of the best foils for a sturdy and stiff growth. An artist painting a picture of a formal entrance to a garden where Hydrangeas and a stiff hedge of Hawthorn grew beside a stone wall chose a position where the light feathery branches of a *Spiraea Thunbergii* swept across the foreground. What is good for a picture must also be good for a garden arrangement." The illustration on p. 85 well shows its value in landscape composition. Mrs. Gifford also notices what we have never before seen stated, that this *Spiraea* is one of the very best of shrubs for planting near the sea. "I have a plant," she writes, "that has grown for several years so near the sea that it is subjected to all the rough usage of wind and storm. Although it appears delicate and fragile, it endures these hardships well, and when it becomes drenched with salt spray it loses none of its brightness, while the foliage of other shrubs and trees near it is blackened and unsightly."

Both the illustrations of this *Spiraea* are from photographs taken by Miss Edith Eliot, of New Bedford, Massachusetts.

VIOLA ODORATA, var. SCHÖNBURNN.—This is a perfectly hardy Violet, which succeeds well under almost any conditions. The growth is low, there are numerous runners, and the flowers are deep blue, small and very sweet. The most abundant bloom comes in early spring, the last of March, or in April, when well-grown plants are a perfect mass of blue. The flowers begin to appear in September, continuing until severe weather, and often during the winter even a few blooms can be picked, with short stems, to be sure, but none the less sweet-scented if they are grown in a sunny, sheltered place and have the advantage of a few mild days. The plants can be grown in masses in the herbaceous border, and these, with liberal treatment, will give the best results. They spread by runners and by self-sown seeds, which latter make the best plants; the only real care required is to foster the production of fresh plants, and even this is generally done by the natural seed propagation. This Violet is a fine plant for the wild garden; it does not dislike a partial shade, and does wonderfully well in grass, if the latter be not too well kept. A pretty effect can be obtained by planting beneath sunny windows, where the Violets will bloom with Crocus and Snowdrops,

and strengthen our realization of spring. A Violet, very much like the Schönbrunn, has lately been grown about Boston, introduced from Florida; it succeeds admirably for forcing in a cold frame; the flowers are larger, the stems longer and the habits of blooming more nearly perpetual. This Violet blooms profusely in the autumn up to the time of heavy frosts. It is sometimes called the Florida Violet, but is as yet little known; it is probably hardy.

VIOLA ODORATA, var. *LEES VICTORIA*.—This plant is old, but little known, and so much resembles the well-known Czar that it is almost impossible to distinguish between them. The flowers are single, deep blue, large, and borne well above the foliage; it is not sufficiently hardy to warrant its cultivation in the open air in this latitude, or at least in New England. Its habits of growth and the liberal manner in which it blooms, throwing a great quantity of flowers within a comparatively short time, makes it an impor-

young plants should be set out in early spring on a warm, sunny slope in well-drained soil; if the season is at all favorable there will be an abundance of bloom from September until severe frost. The propagation is by division; the stubby nature of the growth makes it best to treat the pieces as cuttings and plant them in sand.

LYCORIS SQUAMIGERA.—Under the more familiar names of *Amaryllis aurea* and *A. Hallii*, this plant has long been known in American gardens, chiefly from bulbs distributed by Messrs. Hovey, of Boston, sent them originally by Dr. George A. Hall from China. It has, however, always been a scarce plant owing to the fact that since its original introduction few bulbs have been imported. It is said that the plants have been cultivated for a long time at New Bedford, Massachusetts, from bulbs brought over by one of the old China traders resident there, and in the Manning Nurseries at Reading a mass of them have flowered beautifully every autumn for years. The bulbs here were planted at the base

Fig. 11.—A Flowering Branch of *Spiraea Thunbergii*.—See page 83.

tant plant, and more valuable than the Czar for most purposes. It is highly desirable for blooming in a cool greenhouse during winter, and much better suited for pot-culture than the more commonly grown double-flowered sorts. The treatment is the same that would be given to the hardy Primroses and Polyanthus. Establish the plants in five or six inch pots in early September, and for this purpose plants which have been starved in smaller pots during the summer are often better than the stronger specimens obtained by field-culture. Store them in a cold frame or dry pit; water sparingly, and do not encourage the fall bloom; bring them into a cool house in successional lots any time after the turn of the year. Kept near the glass they will give plenty of flowers for ten days or a fortnight, when they can be thrown away or preserved for blooming another season, the second or even third year's flowering being often very satisfactory. This Violet is also a free bloomer in the open air in autumn; for this purpose

of a south wall, where they have ripened well and proved perfectly hardy. We learn that recent importations by an English firm have made this fine hardy bulb more plentiful, and it is to be hoped that we can soon obtain it in quantity, for there is no doubt of its hardiness here, although it has proved tender at Kew, and is there cultivated in a cold frame. Probably the bulbs do not get fully matured there, for it is well known that many Japanese and Chinese plants withstand more cold here and thrive better than they do in English gardens. A description of *Lycoris squamigera*, with a figure, was published in *GARDEN AND FOREST*, vol. iii., page 176. There is also a colored figure of *L. aurea* in a recent issue of *The Garden*. This *Lycoris* will require about the same treatment as that given to *L. radiata*, or, as it is often called here, *Nerine Japonica*. In structure *Lycoris* is more nearly allied to *Nerine* than to *Amaryllis*, but is quite distinct from both, not only botanically, but horticulturally.

Cultural Department.

A Few New Garden Plants.

OF new plants the principal offerings are, as usual, the so-called florists' flowers, with a few greenhouse and stove plants. Of these it is not my intention to make notes, but only of a few new things, mostly border plants, which are likely to interest the amateur who is looking for flowers which are attractive, but which may or may not be useful according to florists' standards.

The hybrid Briers, originated by Lord Penzance, are to me the most attractive of the new offerings. These Roses have often been described in GARDEN AND FOREST; they were figured in *The Gardeners' Chronicle* in 1891, and were honored with a colored plate in *The Garden*, No. 1105. They were produced by crossing the Hybrid Perpetual Roses, Fortune's Yellow and others, on the Sweetbrier. The new Rose is said to be strong and vigorous, very sweet-scented, and the foliage retains all the charms of the Eglantine, being quite as fragrant.

free growth, this may make a valuable out-of-door plant if well treated.

The Hybrid Tea Rose, Belle Siebrecht, is a Rose of not so rare a color, though of a beautiful rosy pink and excellent in bud and flower. From its parentage, Lady Mary Fitzwilliam and La France, it should make a fine plant for the border; the latter is the best hardy variety here for the production of a constant succession of flowers.

New hardy herbaceous plants seem scarce. I notice only a new seedling variety of the white Japanese Anemone, Lady Ardilaun, which is of Irish origin, and is said to be unusually vigorous, with flowers three and a half inches across, semi-double and faintly tinted with purple on the reverse and on the buds. The prudent gardener will still retain the clump of the old white, for there are few handsomer plants when in flower, and it is of a grace and purity difficult to improve. As this is a seedling of 1892 which is now being widely offered, the rapidity of increase of this Anemone is strikingly shown. A well-colored single pink Japanese Anemone would be a greater gain than any development in the way of dou-

Fig. 12.—*Spiraea Thunbergii*.—See page 83.

The flowers are single or slightly double, and freely produced, of medium size, with prominent yellow stamens, and covering a wide range of most delightful colorings. Some of the varieties produce a second crop of flowers in the autumn, and the flowers usually have a delicate, though penetrating, fragrance of their own which is quite distinct from the odor of the foliage. There are few flowers from which one can gain more pleasing impressions than the single Roses, all of which are distinctly valuable in the garden, whether they be low shrubs or climb over fences or arbors.

The Crimson Rambler is a Japanese Rose of the Multiflora class, which has been frequently mentioned in GARDEN AND FOREST since it was certificated under the name of Engineer, five years ago, and is much advertised at present. It comes with an excellent record as a climbing variety, with its single, but abundant, crop of small double crimson Roses in clusters.

There is at least one first-rate American Rose this season, Mrs. Pierpont Morgan, the cerise sport from Madame Cusin, which is offered as a forcing Rose. With its unique color and

ling. The typical Japanese Anemone is not wanted in gardens, the so-called rose-colored flowers being of a distressing hue—not even an honest Solferino.

New Violets are plants with which everybody experiments very charily or tentatively, for obvious reasons. The new California Violet, which is said to bear very fragrant dark flowers of immense size, on stems ten to fourteen inches long, apparently has merits which entitle it to serious trial.

If Mr. Manda's new Fern, *Adiantum Capillus Veneris imbricatum*, survives the rigor of this winter and its name, its flat fronds and broad pinnæ, like those of *A. Farleyense*, will make it a popular plant for shady places.

It is curious to note the changes in fashion in the Dahlia, though I believe the true Dahlia fancier is wedded to his idols, the beautiful globular flowers, with perhaps a tolerance for the Cactus varieties. A few years ago we had a fancy for the single-flowered kinds, which must be all broad petaled and as circular as possible. We have now arrived at another phase, the novelty of the season having narrow petals reflexed at the edges, and the flowers resembling a wheel without the tire.

There are also some attractive new varieties of Cactus Dahlias, notably a white one, Mrs. Peart.

Cannas are so quickly and readily grown from seed that there is a superabundance of named kinds—mostly of no great merit, but the comparatively recent Königin Charlotte is really a plant of merit and great brilliancy, and will, no doubt, prove of the first order.

At least one house (Henderson & Co.) offers, this season, an important list of early-flowering Chrysanthemums, the best of the Delaux varieties. This is a movement quite in the right direction and offers an opportunity to enrich our gardens with Chrysanthemum-flowers before the heavier frosts set in. Some of these Chrysanthemums produce large flowers, though probably not as big as cabbages, nor with stems like weavers' beams, but they can generally be grown with satisfaction in bush form, and when judiciously disbudded they will produce well-formed flowers.

The early Chrysanthemums do not perfect their growth so much earlier than others, but the flowers come to maturity much quicker after the formation of the buds. In this habit of development there is a most striking difference in the Chrysanthemum varieties.

Elizabeth, N. J.

J. N. Gerard.

Angræcum sesquipedale.

THIS Orchid has now become so common that it is found in almost every collection of this class of plants. Perhaps no Orchid ever caused such a sensation as this when it was introduced, and it has since become famous. It is one of the Orchids Darwin was especially interested in on account of the exceptional length of the spur, and a plant in bloom always attracts attention. This wonderful Angræcum was found in Madagascar by a French botanist near the close of the last century, and when the history of the plants of Madagascar was published in 1822, Angræcum sesquipedale became known to science. Botanists and horticulturists were anxious to introduce it, and many attempts were made, but these were not successful until 1855. Mr. Ellis, a missionary in Madagascar, was fortunate enough to bring home three living specimens to his garden in England, where one of them flowered in the spring of 1857. There was still great difficulty in reintroducing the plant, and for many years it was rare and expensive. In its native country it is said to grow on the trunks and branches of trees, where it has abundant light and air, and in the hottest and lowest districts. A very fine specimen has been in bloom here for more than a month. It is two feet high, and has two branches or stems, which are well furnished with thick, leathery, dark green leaves about a foot long and two inches wide. The flowers are produced on peduncles ten to twelve inches long. When they first appear they are green, and this color continues until the flowers are almost fully developed, when it turns to an ivory-white. As the flowers begin to fade they become pale yellow. The flowers are not very fragrant during the day, but at night they have a strong odor which is not very pleasing. The color and the fragrance of the flowers at night indicate that they are then fertilized by an insect in its native home. The plant in bloom here had sixteen large flowers fully developed at one time; these measured six inches across, and the spurs were twelve inches and a half long. The plant is easy to cultivate. It requires a strong, moist heat, and is grown here in the stove. It also requires plenty of light, but must be shaded from strong sunlight during the summer. It grows well, planted in a basket with crocks and sphagnum-moss, and suspended near the roof-glass. Water must be given during the entire year, and to keep down insect pests the plant must be frequently sponged.

Another large Angræcum in bloom now is *A. eburneum*. It is a large strong-growing plant, with thick, leathery, strap-shaped leaves. The flowers, although not as large as some of the other species, are produced plentifully on nearly erect flower-spikes. The petals and sepals are narrow and green, and the lip cordate and pure white. The flowers are very fragrant, and last for nearly two months. It requires the same treatment as *A. sesquipedale*. It was introduced from Madagascar in 1826.

Botanic Garden, Harvard University.

Robert Cameron.

Amaryllis.

NO bulbous plants show the results of common-sense treatment more plainly or promptly than these, and your correspondent's notes on their cultivation are well timed. Having known the excellent strain referred to, and having raised a number of plants from their seed, I fully endorse what Mr. Orpet says of them. But I would go a step farther and flower the bulbs a month earlier, so as to have a

longer season for growing and maturing. Just here is the point where many have failed in cultivating these plants. After the flower is spent, the plants have been put in a frame or out-of-the-way place to ripen off. The bulb has lost considerably in the production of, perhaps, two spikes of flowers, the soil in the pot is exhausted, when the plant is dried off it is found to be much smaller, and the best it can do the next season is to produce one flower-spike with considerably smaller flowers. Some will not flower at all, but endeavor to recuperate their energies; but with the same result of smaller and weaker plants next year, and flowers unsatisfactory or entirely wanting. Then follows the judgment too frequently pronounced that Amaryllises are not worth growing.

It sometimes happens that very crude methods have resulted beneficially, and my experience with Amaryllis on this line has been very satisfactory. After the flowering I gradually expose them to sunlight and air, setting them in a frame or cool house where the foliage will not get sunburnt. I make sure that their growth receives no check. As soon as the weather permits they are planted out in well-prepared soil in full exposure to sun and receive a mulching of half-rotted manure to prevent excessive evaporation, and to keep the roots cool. They are watered and cleaned as other plants, and the amount of foliage, deep green and leathery, is surprising. The large, fleshy roots cannot be crowded into the pots intended for finishing their growth. Toward the end of the season, and before frost would damage the plants, I carefully lift them and heel them into deep flats and replace them in a cool greenhouse, gradually withholding water when the bulbs will ripen up and they will keep in excellent condition under the stage. Having some long, narrow boxes convenient, I used them, because they were easily laid on the side when necessary to keep dry. When the flower-spike appeared the bulbs were potted up and the same course gone through again.

Seedlings should be pricked off into flats, and as soon as the weather permits they should be planted out in a frame. Later on they can have the full exposure of sunlight and air, and can be treated as other plants. In this way a good collection of Amaryllis can be grown with, perhaps, the least trouble and with excellent results as compared with many other exotics.

Clifton, N. J.

W. Tricker.

Eucharis Amazonica.

THIS is one of the most popular of the bulbous stove-plants, although it is less extensively grown in this country than in Europe. It is indispensable for market purposes where choice white flowers are in demand. Some of the large trade growers on the outskirts of London devote from six to ten large houses to its cultivation to supply the great flower market of Covent Garden. As a general rule, it is grown in pots. These should be of a good size; ten large bulbs should have a twelve-inch pot, and six-inch bulbs a ten-inch pot. The bulbs should be planted quite deep, and they flower best when the pots are well filled with roots. Once in two years is often enough to repot them. Offsets are freely made. These may be potted in six or eight inch pots, from six to twelve bulbs to a pot, and they will soon make flowering bulbs. The compost we find most suitable is two parts of heavy clayey loam and one part well-dried cow-manure; to this is added some broken charcoal and a good dash of sharp sand. The pots should be well drained and the soil pressed moderately firm. When the leaves have completed their growth water should be given rather sparingly—never entirely withheld—and the plants rested in an outer house. When the bulbs are starting a brisk bottom-heat is desirable; with an overhead temperature of sixty-five degrees at night, and a corresponding rise in the daytime a crop of flowers can be had in about a month after the bulbs are planted. Liquid-manure can be given freely as soon as the spikes show, and until the growth is completed, as *Eucharis Amazonica* is quite a gross feeder. If extra fine spikes are desired a piece of bench at the warm end of the stove, or other warm structure, should be used. We use a bench at the warmest end of our Rose-house, and plant in four inches of compost, similar to that recommended for pot-plants, with the addition of some pieces of broken brick. Flowers are not freely produced until the bed becomes a mat of roots. When the plants are well established they should give three crops of flowers a year. Good average spikes will carry from five to six blooms each, occasionally more, with flowers four to five inches in diameter. There are several varieties of *Eucharis* in cultivation, but *E. Amazonica*, called also *Grandiflora*, is the best. Other popular varieties are *E. candida* and *E. Sanderiana*.

A night temperature of sixty to sixty-five degrees in winter, and a bottom heat of seventy-five to eighty-five degrees, suits the plants admirably, although they sometimes do well in a much lower temperature. Abundant watering is necessary in the growing season and frequent syringings. The plants need shade from bright sunshine, but must not be shaded too heavily. Mealy bug and thrips are two of the pests which trouble them. A well-directed force of water from the hose will keep both in check. If they have been allowed to get a foothold, fumigation will destroy the thrips, while sponging with some kerosene emulsion or Fir-tree oil, dissolved in water, will be found the most effectual way to get rid of the mealy bug. Should the Eucharis mite make its appearance all affected plants must be thrown away. We have seen many less heroic remedies tried to get rid of this mite, but none have been successful.

Taunton, Mass.

W. N. Craig.

Violet Notes.

MUCH has recently been written on the Violet and its liability to disease, and it is generally admitted that there is no cure for the dread spot when once it has got well started. We have had considerable trouble in fighting off this disease, and have come to the conclusion that enough runners pulled off in the fall to supply plants required for the next year's crop should be kept in a cold frame all winter. In this way the stock will become strong and vigorous and better able to withstand the attacks of disease should this appear. Our plants are, in every way, better this winter than we have ever had them before, and the crop of flowers is much larger. These plants have not been subjected to fire-heat for three generations, and we hope in this way to keep them altogether free from disease. It is not fair to subject Violets to the heat of our cool greenhouses even as they are kept in the spring months, and after the plants have been forced to produce big crops, to take off stock for the ensuing winter and subject this stock to the excessive heat of our summers. The boxes of cuttings are frozen for several weeks in severe weather in the frames, but if they have made roots in the fall this does not injure them in the least, and they remain there until planting-out time in May, thus saving much valuable time and space in the greenhouse in the busy spring months.

The Violet known as the Farquhar is identical with the kind long grown, both here and in English gardens, under the name of New York, and it would be interesting to know more of its origin. That it is a sport from the well-known Campbell can scarcely be considered, it being in every respect a direct antithesis to that variety, and resembling much more the Marie Louise; indeed, it is hard to distinguish between Farquhar and Marie Louise as usually grown.

If Marie Louise will do well, there is no other kind as good. Growers recently had an opportunity of noting their excellence when these flowers were exhibited in Boston by Mr. Mackay, of Framingham, Massachusetts. They had been grown in pots in a cool house and were of superb color, large size, and very fragrant. As long as such fine flowers can be grown there is still a future for the old Marie Louise.

South Lancaster, Mass.

E. O. Orpet.

Chrysanthemums.

AS the season for the distribution of new Chrysanthemums approaches, some suggestions as to their treatment may be timely. The stock sent out now is better than that of a few years ago, owing, in a measure, to competition, but due even more to careful attention to the time of propagation, so that the plants are brought into good condition at the time of distribution, and also to a better general knowledge of their cultivation. Formerly we had a considerable proportion of overdrawn plants, grown crowded and pot-bound. A small percentage come in that condition now, but the majority are dwarf, healthy plants in a growing condition, showing that they have been struck and rooted as they should be—within a period of five or six weeks. It is hard to deal with a woody pot-bound plant. The best thing to do is to take the tip out, and this will probably make a better plant than the original would have made under equal conditions. We may force a few cuttings out of the remainder of the plant in a warm moist house or a propagating-frame. With younger plants the task is easier. The treatment must depend upon whether the object is specimen plants or blooms. For a specimen plant we take out the tips merely, thus inducing it to break freely; for at all stages the softest wood always breaks best, and, therefore, during the whole season, if neat bushy specimens are desired, the shoots must not be allowed to run on for a week or two, and then be cut off six or eight inches, but they must be

stopped every day. For specimen blooms we cut the plants in rather hard, so as to get suckers, if possible, since these make the best cuttings for blooms. In doing this it should be remembered that good plants can be raised from leaf-eyes. Occasionally in cutting down a novelty we have managed to get three or four leaf-eyes in addition to the tip, which we have sometimes had to secure with a piece of bast to make it firm in the cutting-bench; such a cutting will root with as much certainty as any others.

It often happens that in packing for shipment the balls are pressed hard when the soil is wet, to keep the roots together and to keep them from drying out. This solid ball should be removed and the plants put into loose soil composed mainly of leaf-mold and sand. The plants intended for specimens we put into three-inch pots, and gradually shift them along in the ordinary way as they become rooted. Stock intended for blooms we put into ordinary flats, and if given room enough they can stay here until the season for striking cuttings is past, which will not be until the first week in July.

Our plants intended for specimen plants have lately been put into three-inch pots. In the course of three or four weeks they will be rooted sufficiently to have another shift, a little heavier soil being used this time. Our stock in frames will soon begin to move as we admit sunshine and air; those in the cool greenhouse may be cut down early in March, and these will furnish a good crop of root-cuttings in May.

Wellesley, Mass.

T. D. H.

Grapes under Glass.

THE second house may now be got ready and started for a successional crop of grapes. In the first house, started at the end of December, the eyes are now well advanced, especially those of the Black Hamburg variety, which is always the first to start, and disbudding should be begun as soon as the strongest shoots can be distinguished. These are in all cases selected, although one is often tempted to sacrifice a strong shoot if it is far from the rod, for the sake of keeping the spurs short; but it must be borne in mind that in doing so a better bunch of grapes is also sacrificed. One shoot is left to each spur, and we find this quite enough, though some growers leave two. This is undoubtedly a mistake, as it causes overcrowding of the foliage and otherwise impairs the vine. One healthy, well-developed leaf is preferable to a dozen weak, overcrowded and sickly ones, and upon the foliage, to a great measure, depends the success of the crop. Tying down should never be attempted until the shoots are strong and firm, as they are easily broken off at the joints, and should be brought down to the wires gradually and carefully. Pinching must soon be attended to. Several bunches will form on each shoot, but all should be removed, with the exception of the strongest, which is generally, though not always, the one nearest the rod. After the bunch has been selected the point of the shoot should be pinched out two joints beyond it. In the case of young vines the leaders are allowed to run, the length being regulated according to the dimensions of the house. A top-dressing of fresh cow-manure is then given, and well watered in, as this watering will have to carry the vines past the flowering and setting stage. A thorough soaking is given, after which the atmosphere of the house is gradually dried up and kept dry through the flowering period. The pollen is thus kept dry, and the free setting of the fruit is promoted. As soon as the fruit is set the syringe must again be used freely, and the atmosphere kept moist to prevent the attacks of red spider and thrips. The latter is probably the most troublesome of all insect pests that attack the Grape-vine, and a sharp lookout must be kept to prevent its getting a hold. It makes its first appearance either at the top or bottom of the rods, and as soon as it is seen we syringe the infected parts with a solution of antipest, which we try to keep off the fruit as much as possible.

William Scott.

Correspondence.

Inscriptions on Public Monuments.

To the Editor of GARDEN AND FOREST:

Sir.—You explained some time ago the superiority of the statue of Nathan Hale as a work of art to most of the others which profess to adorn New York, and you noted the fact that its excellence was instinctively recognized by the public, so that it is a source of genuine popular instruction as well as delight, while its inferior rivals neither please the eye nor inspire the soul. May I add a word with regard to the matter of inscriptions upon public monuments, as no better instance of

a good one could be found than that upon the base of the Hale statue? It runs thus:

"Nathan Hale, a Captain in the regular army of the United States, who gave his life for his country, in the city of New York, September 22d, 1776. 'I regret that I have but one life to give for my country.' Erected by the Sons of the Revolution of the State of New York."

This, I think, supplementing the dramatic expressiveness of the figure itself, tells enough to satisfy, for the moment, any person, if such there be, to whom Hale's name is strange, and tells it in such a way as to excite sympathy and interest. Besides this, it contains no superfluous words, and has the literary merit of directness and conciseness. And the quoting of Hale's own words is a proper tribute to their fame as well as to his character.

In contrast to this the inscription on the base of the statue of Ericsson, in Battery Park, is as inadequate as is the statue itself. The name is on the front of the pedestal, and on the back we read:

"The City of New York erects this statue to the memory of a citizen whose genius has contributed to the greatness of the Republic and to the progress of the world."

These words tell us nothing that we should not have known without them. It is presupposed that every citizen to whom a statue is erected in a public place has well served his compatriots, and through them the world at large. But there are many kinds of genius, many ways of being serviceable. An inscription which might with equal propriety serve on the memorial of any other noted American was not worth the trouble of writing. What was needed on the Ericsson monument was something specifically explanatory of Ericsson.

I know that we are sometimes told that no monument ought to bear anything but the name of the man whom it honors; in other words, that no man deserves a public monument whose identity is not known, whose services are not familiar to all his fellow-countrymen. But I think, under any conditions, this is an exaggeration of the broad truth that only real servants of the public deserve to be publicly commemorated. And certainly it is not a code of procedure to be acted upon in a city so big and so cosmopolitan as ours. Washington, Lincoln, Grant—men like these do not need to have their identity explained, for every one, even the newly landed foreigner who has any intelligence whatever will have heard as much about them as an inscription could tell. Even in such cases a few pregnant words on a statue's base, especially if they were once uttered by the man commemorated, often help to arouse the imagination and quicken the pulse. But we must have many foreigners, many school-children, and possibly some adult Americans even, who are not familiar with the names of Hale, Greeley, Seward, Ericsson, Farragut and many another man who is worthy of a public memorial. We are not likely to have too many statues, provided we erect none which are not genuine works of art; and, when they represent men about whom the slightest doubt may exist in the mind of the humblest passer-by, let them bear some words of terse suggestion or explanation. But to be of this kind the legend must be definite, certainly not vague; and it ought, of course, to be free from such verbal faults as may be noted in the Ericsson inscription, which says "whose genius has contributed—" although referring to a man whose genius is no longer at work. Again, it ought to be in plain sight and easily read. I have found from observation that few persons discover anything more on the Ericsson pedestal than the mere name in front; and even if one does examine the back, the lettering is not readily deciphered. On the other hand, the Hale inscription is on the front of the pedestal where no one can miss it; and it is so plainly printed in raised letters of bronze applied to the smooth granite that every one must see and read it.

I am not discussing just now the artistic merits of our monuments, else I might well enlarge upon a theme already familiar to the readers of GARDEN AND FOREST—the degree to which the right effect of a figure depends upon the appropriateness and the beauty of its pedestal. This point, again, could not be better illustrated than by the base of the Hale monument. Its circular shape, so well suited to the composition of the lines of the figure, the delightful color of its reddish granite, and the refined character of the architectural details, are not more remarkable than the skill with which the inscription has been applied, so that it charms the eye even before it speaks to the mind. But the public may be trusted, I think, to appreciate the excellence of this pedestal, as well as that of the statue it bears, and to apply the standard thus set to all future memorials which may be erected in New York. I will only add that, while every one is aware that the statue is the work

of Mr. McMonnies, it may not be as generally known that the design of the pedestal and its inscription is due to Messrs. McKim, Mead & White.

New York.

M. G. Van Rensselaer.

The Effect of Bad Seasons on the Growth of Trees.

To the Editor of GARDEN AND FOREST:

Sir,—In the course of the study of Spruce-timber in the state of Maine, data have been discovered which illustrate strikingly the effect of the weather upon the growth of trees. The most satisfactory evidence of this kind is a band of very thin rings in the trees throughout the region, these rings corresponding with a series of cold and stormy years known to have occurred in the early part of this century.

There is abundant testimony to the inclemency of the years during and immediately following the war of 1812. Their unusual severity in the state of Maine is established from a variety of sources. Meteorological records kept by Professor Parker Cleveland, of Bowdoin College, prove the general low temperature of these years, while histories of the state and of different counties, private records and oral testimony tell reliably of the storms and frosts, which probably were responsible for the effects upon vegetation to a greater extent than the general low temperature. The seasons of 1812, 1815 and 1816, however, seem to have been the most severe. In the two last named almost no crops were raised in Maine, the year 1816 marking the culmination of the series. A considerable snow fell about the 10th of June, causing the leaves to fall from the deciduous trees in some regions, while frosts and ice are said to have formed in every month of the year. It must be distinctly stated, for reasons which will appear later, that 1812 was the first of the inclement seasons, while the year 1817, on the other hand, was the last which by any means can be included in the series.

Turning now to the record left on the trees by these cold seasons, it is to be said that throughout the state the older trees* uniformly show it. Generally six or seven rings are thinned. As few as three have been noted, but more frequently the rings concerned overrun the usual number. Generally, the belt is very plainly marked, the rings being reduced to but a fraction of their usual thickness. Frequently within the belt there is a group of three rings reduced nearly or quite to microscopic dimensions. This feature is so striking, and has been so widely formed, that the conclusion has been inevitable that the phenomenon is due to some common cause. This cause, not improbably, was the severe weather of 1816, stopping growth and causing the deposit of the small-celled wood characteristic ordinarily only of the autumn. On this supposition, the year 1816 might have grown all three of these rings.

Confidence that the facts have been rightly interpreted is established by the size of the region through which the thin rings have been found. My investigations have extended across the entire state of Maine, from the New Brunswick line into northern New Hampshire and the White Mountains. Having personally counted the rings of some 1,400 Spruce-trees throughout that region, I believe it is a fact that east of the White Mountains I have never looked for this record and failed to find it in a tree that eighty years ago was in condition to receive it. Some trees on the high slopes of the White Mountains do not show this feature, but it seems probable that their exposed situation may be the explanation of this, and not that they are on the boundary of the region in which the cold years were felt.

One more matter remains to be treated—the position of the belt in the tree. Most of my observations were made in the winter of 1893-4, between which time and 1817, seventy-six seasons of growth had passed. Supposing, then, that no effect of the cold years held over into succeeding ones, the first ring that is distinctly thinned, in case each year deposits a single ring, should be the seventy-seventh from the bark. This is, in fact, sometimes the case, but far more frequently the thinning begins nearer the heart. Reckoning from the inside of the belt, and from the rings just identified with the year 1816, a similar result is reached. The rings are too many to correspond with the years, the discrepancy in most cases amounting to three or four. The conclusion, from the data gathered seems to be that, even in ordinary seasons, most or all of our forest Spruces deposit occasionally an extra ring. This is an important physiological fact, and it is at variance with accepted

* Spruce only is included in this statement. Of other species a few Hemlocks examined showed the same thing, while Pines examined in larger numbers, and in a variety of conditions, do not show it. Belts of thin rings are found, but, maintaining no constant position, they are judged to be due to individual causes.

ideas in the matter. Disks of Spruce were cut from the region of Moosehead Lake, in Maine, and from eastern slopes of the Presidential range, in New Hampshire, and sent to the United States Forestry Division for testing their strength. When examined by the Division most of these disks which show the full number of rings to correspond with the cold seasons have eighty rings outside of all the perceptible thin rings.

Evanston, Ill. Austin Cary.

[To substantiate his view Mr. Cary sends a table, compiled from his own notes, on the measurement of these disks. It is only necessary to add that the figures substantiate what has been said. In most cases the widest one of the zone of narrow rings measures half a millimeter, the narrowest ones about a quarter of a millimeter, while the nearest ring on the inside or the outside of the zone averages a full millimeter in width.—ED.]

Meetings of Societies.

The American Carnation Society.—I.

THE annual meeting of this society, which was held last week in Horticultural Hall, Boston, was only its fourth one, but the number of delegates and visitors and the size and completeness of the exhibition would have done credit to an association of much greater age. Mr. Eugene Dailedouze, the President, frankly stated that the hope of obtaining new varieties was the life of the organization. Both flowers and plants had been improved much in the past, but still they were in search of others superior to anything yet possessed, and, so long as they were inspired by the prospect of success in this direction, the society would continue vigorous and progressive. All the best commercial Carnations are worth a good deal apart from their exhibition value, and Mr. Dailedouze offered some suggestions as to the best way of finding out the full merits of new plants as all-round varieties. He advocated the plan adopted by the Chrysanthemum Society of appointing reputable judges in different parts of the country where Chrysanthemums are produced largely, who, without favor or prejudice, can pronounce judgment on new plants at their homes. Judges at these Carnation centres should see the plants at least twice during the season while they are growing, so that they can report at the annual meetings as to their habit and general qualities. This would enable the judges to observe the weak points of a plant as well as its good ones. No one can estimate the merits of a plant simply from seeing a cluster of its flowers on an exhibition table. The President also suggested the offering of gold and silver medals for new varieties, and advised that no medals should be given for a variety unless it had been tested in five or six distinct localities and reported on at the annual meeting. This would give an idea of its general usefulness and decide whether it had more than local value. Persons who are testing new varieties, and writing of them, ought to describe the house in which the plants are grown, the composition of the soil, any special conditions of their cultivation and the varieties which they most resemble in good or bad habits. He gave many examples of plants like Mrs. Fisher, Lizzie McGowan and Tidal Wave, which are not good in some parts of the country, while they are extremely useful in others. In his opinion fifty blooms at least of a new variety should be shown when competing for a prize. This requirement ought to be no hardship, because no one would think of disseminating a new variety unless he had a thousand plants of it, and if fifty exhibition blooms cannot be secured from that number of plants the variety is not worthy of being put on sale. He also advocated the showing of plants of new varieties as well as their cut flowers, so as to afford an opportunity for observing their habit and character of growth. He also thought that new varieties which had been grown under glass all summer, when exhibited, should be put in a separate class from those which had grown out-of-doors. He did not agree with the statement that certain plants should be grown for cut flowers, and others should be used for cuttings. A Carnation is in its best possible condition when producing the best flowers, and cuttings from such stock ought to be the best that can be secured. No science can be displayed in growing Carnations for cuttings, but the test of skill lies in producing good flowers. No poor or half-grown plants ever throw first-class flowers.

In Mr. Lonsdale's paper, which discussed alphabetically sixty-seven different varieties, noting their good and bad qualities and pedigrees, and explaining why some had been superseded and others had remained popular, he stated that several

varieties had been so long before the public as to discredit the prevailing opinion that a variety of Carnation is necessarily short-lived, and that new ones must be constantly produced simply to take the places of those which die out. Buttercup had been grown, for example, for nearly twenty years, and it is still in the front rank. This is a variety with which Mr. Lonsdale had never been successful until three years ago, when he began to keep it under glass all the time, and since then it had done admirably. He thought that many other varieties which had failed in different places might show themselves of great value when treated in the same way, just as Roses and Chrysanthemums are. Some remarkable prize-winners, like Grace Battles and Edna Craig, are now rarely seen because they are subject to disease. One variety, named Sea Gull, which won a gold medal at New York three years ago, when it defeated Lizzie McGowan and sold for a good price, was found on trial to be so worthless that it was never sent out. This shows the need of some radical change in the method of judging novelties.

Professor Halsted, of Rutgers College, read a paper on the fungous diseases which attacked Carnations, describing the rust, the leaf spot, the black speck, the ring mold and bacteriosis. He had specimens of each of these principal enemies of the Carnation placed under the microscope so that they could be studied and detected. He stated that there were other diseases which attacked the Carnation, but these five were those which were to be expected and which must be contended with. He recommended every grower to keep on hand a good description of each of these diseases and to examine every affected plant with a hand lens, or, if possible, with a compound microscope.

Mr. John N. May's new seedlings, Maud Dean, Lena Saling and Dean Hole, which we have already described in this journal, received certificates of merit. Certificates were also given to Storm King and Meteor, exhibited by the Cottage Gardens, Queens, New York; to Aramazinda and Triumph, exhibited by E. G. Hill & Co., of Richmond, Indiana, and to Della Fox, exhibited by Myers & Santman, Chestnut Hill, Pennsylvania. The committee commended the last firm for sending a plant of Della Fox to the exhibition, and a plant, too, which had been grown on a bench and not in a pot, so that they could judge very well of its character for commerce. The exhibition was admirable in quality, and, besides the Carnations, there were enough Palms, Orchids and other plants contributed by Mr. John L. Gardiner, Mr. N. T. Kidder and others to serve the purpose of general decoration. In the class for one hundred blooms the plants which won were: Alaska, white; William Scott, light pink; Tidal Wave, dark pink; Jubilee, scarlet; Ferdinand Mangold, crimson; Buttercup, yellow; Minnie Cook, variegated. For fifty blooms, the prizes were gained by Storm King, white; William Scott, light pink; Jubilee, scarlet; Meteor, crimson; Bouton d'Or, yellow, and Helen Keller, variegated. A special premium, offered by the Florists' Exchange for a vase of flowers showing the best culture, was given to Edwin Lonsdale for a group of variegated flowers of Helen Keller. In the report it was stated that the premium was awarded to Mr. Lonsdale because the variety was difficult to grow to such perfection, and, therefore, it showed the highest color. Equally well-grown plants were shown by Dailedouze Brothers and H. K. Southworth, the latter with the yellow-flowered Buttercup. The other leading prizes were taken by W. E. Chitty, Dailedouze Brothers, E. G. Hill & Co., William Nicholson, H. K. Southworth, C. W. Ward and Fred Dorner.

New York was selected as the place for holding the next annual meeting. Fred Dorner, of Lafayette, Indiana, was elected President; John N. May, of Summit, New Jersey, Vice-President; A. M. Herr, of Lancaster, Pennsylvania, Secretary, and Charles H. Allen, of New York, Treasurer. A committee, consisting of A. M. Herr, Edward Lonsdale and Robert Craig, were appointed to revise the list of Carnations, to strike out the names of varieties no longer grown, and prepare a new working list.

For lack of space our notes on some of the new varieties, and on a few of the standard sorts as well, are postponed until next week.

Notes.

Following the example of the common garden Pea, a sport of the Sweet Pea seems to have abandoned its climbing habit and developed a dwarf variety which grows only five inches high, making a low tuft of short branches, which bear white flowers for an unusually long period, and in such quantities as to cover the plant. The plant is named Cupid, and Burpee

& Co., of Philadelphia, announce that it will be distributed next year.

A statue has recently been erected at Montpellier, in the south of France, to commemorate the life and services of the distinguished botanist, Gustave Planchon, to whom, after a study of the phylloxera on American Grape-vines, was largely due the rehabilitation of the Vines of France after they had been ravaged by that insect. It is the work of the sculptor Baussian, and represents a laborer offering a Vine-branch to Planchon.

Small compact plants of *Spiraea Thunbergii*, of which we have spoken on another page of this issue, have sometimes been used for winter-forcing with good effect, and we have lately seen some good branches of this plant which made a fair show of flowers when placed in water. The buds are fully formed in autumn, and its habit of early flowering is often indicated by the white blossoms which it bears during mild days in November.

Cos Lettuces have never been as popular in this country as they are in Europe, although for flavor and tenderness the best of them are superior. Of course, they form no head, but if the leaves are gathered up and tied the inner ones will soon become blanched and brittle. A correspondent of *American Gardening* has found that a slender rubber band slipped over the outside leaves of the plant will answer every purpose, and, of course, this is much more expeditious than tying.

A bulletin from the Agricultural College of Texas, which treats of fruits for that state, gives the information that native Plums of the Wild Goose group and of the Americana group do not seem so well adapted to Texas as those of the Chickasaw group. The European varieties have almost entirely failed. Japanese varieties also seem to do well. The Kaki, or so-called Japan Persimmon, is also promising, and thrives well in Texas when budded on stock of the native wild Persimmon.

There seems to be no end to the problems which confront workers in the higher branches of horticulture. Some men of science in France have been making a study of plants grown from the seeds produced on grafted plants, and they seem to have demonstrated that the seedlings may partake of the character of the stock as well as of the cion—that is, a seedling from a graft may be, in a certain sense, a hybrid inheriting the qualities both of the plant which is used as a cion and the plant used as a stock. These experiments have been confined to herbaceous plants, and they show that, for example, when a Turnip is grafted on a stock of Garlic Mustard, plants from the seed showed a marked reversion to the wild type, and when this Garlic Mustard was grafted on Cabbage the seedlings showed a likeness to the Cabbage-plant, and had a less marked smell of garlic than the wild plant, combined with something of the odor of the cabbage-leaf. Of course, if this is true, it is not improbable that the same law holds throughout the vegetable kingdom, and when, for example, we cross two varieties of grafted Apples the seedlings may show not only the characteristics of the parent plants, but of the cions upon which they grow. In this way a hybrid Apple may have four parents, to each of which it is responsible for some of its characters, not to speak of the qualities it may have inherited from the numerous ancestors of each of these parents.

Dr. Hoskins has been giving instructions about planting orchards in northern New England, and some of his advice, while by no means new, cannot be too often repeated. Much depends on getting first-rate trees to start with, and the stock should be bought, therefore, of a trustworthy firm and not of traveling peddlers, who too often supply poor trees of poor varieties in poor condition. When taken from the nursery as much of the roots should be taken as possible, and in an unmangled condition, but where their ends are bruised they should be trimmed smoothly with an undercut with a sharp knife. They should be planted as quickly as possible in their natural position, with the roots sloping downward somewhat from the trunk and with fine soil carefully worked in about the fibres, and firmly set with a slight inclination toward the southwest, otherwise the prevailing wind will bend them as much the other way in a few years, and the hot sun will injure the bark on that side of the tree. The first point in the selection of a position for an orchard is to have good soil. An Apple-tree has not only to grow, but it has to produce abundant fruit if it will pay. The tree may appear to thrive when it has not much nutriment for a while, but as it increases in size it will demand more food, and if it does not get enough it will have a scrubby growth, even before it comes into bearing. Where land has been run down it must be enriched until

it is good enough to give a crop of Corn, and unless a young orchard makes an annual growth of, at least, a foot of new wood every year, the ground should be manured thoroughly.

In a recent address, Dr. E. H. Jenkins, of the Connecticut Experiment Station, argued against the usual practice of estimating the value of stable-manure simply from its contents of nitrogen, phosphoric acid and potash. Stable-manure contains elements of value to soils which chemical fertilizers cannot supply, and without which they cannot produce their full effect. These elements regulate the heat and moisture of the soil, together with its powers of nitrification. This organic matter produces the black mold which holds water, makes leachy soils retentive of moisture and keeps other soils, in which chemical fertilizers are used freely year after year, from becoming hard and cloddy. This humus is a specially valuable part of manure, because we do not get it in commercial fertilizers, and we cannot get it in any other way in such good condition as we can through the manure pile. These facts emphasize the importance of a supply of litter in the stable, not only as an article of comfort and cleanliness to animals, but because it adds largely to the value of the manure decaying along with it and performing an important use in the soil. Stable-manure exposed to leaching and drainage will lose the greater part of its value, and even in a tightly packed pile one-quarter of its nitrogen and one-third of its organic matter may be lost by fermentation in half a year. Kainit, where the manure is to be used on sandy soil, and superphosphate gypsum, where the manure is to be used on heavy soils, when mixed with the manure pile, will entirely prevent the loss of nitrogen and largely preserve the organic matter. A mixture, in the proportion of four parts of dissolved phosphate rock with three parts of plaster, should be used at the rate of one to one and a half pounds a day for each head of stock, and when kainit is used the proper amount is from one and a half to two pounds a day.

But for the two disastrous periods of zero weather which desolated the Orange groves of Florida the market here would now have been well supplied with fruit from that state. Probably the number of oranges destroyed in Florida would amount to as many as the entire California crop, which is arriving under the most favorable conditions for profit to the growers. The great bulk of the supply from the West Indies is already here, although these islands will provide limited quantities for a month to come. The Valencia fruit has been injured by cold, and the season for Sicily oranges will not be at its height until the larger part of the California supply will have been marketed. And yet choice fruit from California commands little more than it does in ordinary seasons. A very limited supply of hot-house strawberries and hot-house grapes can be disposed of at fancy prices, but the great mass of buyers will only pay reasonable rates for fruit for daily consumption, and they will go without oranges rather than buy them at \$5.00 a box, however high their quality. It should be said, too, that the California fruit is unusually good this year. There has been no chilling weather on the Pacific coast, so that the oranges are more juicy than they usually are, and the crop this year is said to be the best in color and quality ever sent to the east. Perhaps the dry and cottony quality of California oranges in some former years has prejudiced New York buyers against them, and the fact that frozen and, therefore, worthless fruit from Florida has been sold to some extent, has also made them cautious. However this may be, the best California oranges are not realizing what they would naturally be supposed to command under the present remarkable conditions. Nevertheless, the oranges which are arriving here at the rate of twenty to twenty-five car-loads a week, are all disposed of at good prices, and the lower grades are selling for more money than in ordinary years. Altogether, then, the California fruit-growers have nothing to complain of, and it is probable that if the Florida supply had been uninjured the year would have been a disastrous one to them. Oranges from Jamaica, Havana and Abaco, one of the Bahama Islands, and from Sicily are selling well, but the fancy fruit of the season, no doubt, comes from California. A few heads of cauliflower which came from California with the first shipments of oranges found a ready sale, and owing to the good quality and the dearth of fresh vegetables from the south, cauliflower is now coming across the continent by the car-load. Large, bright heads sell at retail for fifty cents each. Artichokes from southern France and Algiers are in good supply, and sell at twenty-five cents each. String-beans are coming from Bermuda, and all northern-grown hot-house vegetables are in good demand and profitable to the growers.

City Engineers and Public Parks.

THE new Mayor of this city, acting under powers conferred on him by the recent legislation, has removed the entire park commission and appointed a new board. The old board have forfeited public confidence in many ways, but their most serious offense was that in the construction of a pleasure drive along the shores of the Harlem River they refused to consult with their landscape-architect, and directed a city engineer to prepare plans and specifications and carry on the work. The people of this city have come to understand that public grounds as surely demand artistic treatment as public buildings do; and that to entrust the planning of a public park to one who is not skilled in landscape design is as much an outrage against civilization as it would be to erect a municipal building without an architect. It is a pleasure to announce that the new board has taken the earliest opportunity to put the speedway under the supervision of Mr. Vaux, and to order the engineer in charge of the work to report to him. This elevates the skilled park-maker of the department to his proper rank at the head of these works as their designer, and places the engineer where he belongs, subordinate to him and in charge of matters of construction under his direction.

Now, we may conceive of an engineer who has a feeling for landscape, and who carries on his work with due regard to its effect upon the scenery, but his education would naturally give his mind another bias. When told to construct a road between two points, nothing in his professional training leads him to make any effort for harmonizing his work with the landscape. He often takes pride in making it obtrusively distinct from nature, since in his view, and this is in a manner a true view, it has a beauty of its own which should be displayed. It is his business to make a convenient road and build it as economically as possible. What he aims at is to facilitate traffic between two points, and he is not to be lured from his professional duty by any appeals of natural beauty. Naturally, a man whose entire training and practice has led him to ignore the element of natural beauty, would be the last one to select

for laying walks and drives in a park, for here this beauty is of paramount importance. These roads and walks are not for traffic; they are not primarily for pleasure, driving or walking, but they are prepared, as the shelters and seats are, to enable the greatest number of people to enjoy the beauties of the scenery with the greatest comfort. A park road, therefore, which needlessly mars the landscape, defeats its fundamental purpose. Of course, we are now referring to park work in general, and not especially to the Harlem Speedway, in which the road is the essential element.

No doubt, the plans of the speedway will have to be revised. If proper professional advice had been taken before the work began, much of the picturesque slope above its line would have been purchased by the city, so that it could have been used to add to the dignity of this unique water-side parkway, which, with proper treatment, could be made one of the most beautiful of the city's possessions. Certainly, on the sidewalk along the river provision must be made for ample space and enough soil for a row of trees, without which the road will be altogether commonplace and incomplete. To change the plans will cost the city something, but self-satisfied ignorance, in responsible places, is always expensive to the people. It is to be hoped that the new Board will not shrink from the additional duty which the blunders of their predecessors have thrown upon them, but will attack the work with intelligence and resolution.

We may add here that a large proportion of the cities of this country have no professional landscape-designer, and public parks and grounds are all under the charge of a city engineer. Naturally, the result is painful to every one who is qualified to pass judgment on a landscape. Apart from the fact, as we have stated, that his training has all been directed to give him skill in another direction, there is another mistake which the city engineer almost invariably falls into when he becomes a maker of parks. This trouble, as tersely stated by Mr. John C. Olmsted, in an article lately published in the *Journal of the Association of Engineering Societies*, is, "that he is often disposed to solve the problem presented by each element of a park independently of every other." That is, he will lay out a new piece of road one year, he will build a conservatory or dig a pond the next, and he will carry on each fraction of the work in a way which seems most convenient and economical considered by itself without any comprehensive idea of the influence that these separate features will have upon each other, or upon the park as a whole. Such work must, of necessity, be unrelated and inconsistent. No city would think of erecting a municipal building without some architect to make a general plan, or without knowing what the various apartments are to be used for, or what sort of necessities are to be provided for, and yet it would be quite as sensible to start a city hall without any plan or to permit radical and inharmonious changes in it while the building is in course of construction as it is to fritter away money on park construction in a fragmentary and disconnected way instead of working steadily toward the ideal of a competent designer.

Wherever parks must be entrusted to a city engineer, the man selected should be one of broad training and liberal education, as well as technical knowledge within the narrow limits of his profession. He ought to understand not only that every park should have a plan with consistent features and unity of motive, but he ought to know enough to treat different ones so that each shall supplement the deficiencies of the rest, so that all may stand properly related in a comprehensive and harmonious park system. Men who are endowed with the creative faculty united with a genuine feeling for the aesthetic and poetic value of scenery are rare, indeed. When they appear, their best efforts are too often unappreciated and neglected. In more than one city in the United States and the Dominion of Canada designs of parks, prepared by real masters, have been nominally accepted, and then so warped

in construction from their original meaning and purpose that they are not even good parodies of the artist's ideal.

SINCE the foregoing was in type the engineer in charge of the Harlem Speedway has expressed resentment at being considered subordinate to the landscape-architect, and has sent a letter of resignation to the Park Board. This resignation was not accepted at once, as would have been expected, and the Board passed a resolution with the apparent purpose of limiting the power of the landscape-architect. This resolution places him in charge of the "landscape and architectural features of the work subject to the supervision and approval" of a committee consisting of Mr. Frederick Law Olmsted, Mr. Augustus St. Gaudens and half a dozen distinguished architects. Of course, this was not a well-considered step. It degrades the position of landscape-architect from what ought to be its true rank in the well-ordered system of park management. It is an indignity laid upon Mr. Vaux personally, in that it assumes beforehand that his work needs supervision. It assumes that a pleasure-ground need not be a consistent work of art with unity of motive and purpose, and that it is possible to separate such a work into its elements with an engineer to make the roadway, an architect to build the walls and a gardener to treat the landscape, each one working without regard to any comprehensive and congruous plan. Fortunately, the gentlemen who constitute the new Park Board are men of integrity and intelligence, and, therefore, there is no reason to fear that they will cling obstinately to this erroneous conception. After they have given more study to the matter, and the full light of public discussion has been turned upon it, we may expect them to abandon the untenable position they now hold.

Notes on North American Oaks.

Quercus Toumeyi.—I propose this name for a small White Oak* discovered in July, 1894, by Professor J. T. Toumey, of the University of Arizona, on the hills above the mining town of Bisbee, among the Mule Mountains, in south-eastern Arizona. It is a tree twenty-five to thirty feet in height (see figs. 13 & 14 on pages 94 & 95 of this issue), with a short trunk six to ten inches in diameter, dividing near the ground into spreading limbs, which form a broad, irregular head. The bark of the trunk is about three-quarters of an inch thick, deeply furrowed, dark brown tinged with red, and broken on the surface into small, thin, closely appressed scales. The summer branchlets are light red and more or less covered with pale tomentum, and in their second and third years are slender, with thin dark brown, nearly black bark divided into small plate-like scales. The leaves are crowded at the ends of the branches, oblong or ovate, rounded or cordate at the base, acute and apiculate at the apex, entire with thickened revolute margins, or remotely spinulose-dentate, or often minutely three-toothed at the apex, thin and firm, light blue-green, glabrous and lustrous above, pale and pubescent below, from one-half to three-quarters of an inch long, from a quarter to a half of an inch broad, conspicuously reticulate-venulose, with slender midribs raised and rounded on the upper side and thin arcuate primary veins; they are borne on short petioles about one-sixteenth of an inch long and probably fall early in the spring with the appearance of the new growth. The flowers are unknown. The fruit is sessile, solitary or in pairs, and ripens in June; the nut is oval or ovate, from one-half to two-thirds of an inch long and a quarter of an inch broad, light brown and lustrous, covered at the acute apex with pale pubescence, and glabrous on the inner surface; the cup, which encloses less than a quarter of the nut, is thin and shallow, cup-shaped or

turbinate, light green and pubescent within, and covered on the outer surface by thin ovate acute regularly and closely imbricated light red-brown scales with short rounded tips and coated on the back with hoary tomentum.

Quercus Toumeyi forms on the Mule Mountains the principal part of the narrow forest zone immediately above that in which *Quercus Emoryi* is the principal tree, the two trees mingling toward the lower margin of the belt of *Quercus Toumeyi*. Among North American species *Quercus Toumeyi* most resembles some of the spinescent or entire-leaved forms of *Quercus undulata*, from which, however, it differs in the dark brown deeply furrowed bark, that of *Quercus undulata* being ashy gray or light reddish brown and scaly, in the nearly black bark of the branchlets, the thinner and less pubescent leaves, and in the thinner cup-scales.

Quercus Grisea.—Liebmamn's type of this species, collected near El Paso by Charles Wright, shows that, as Engelmann always believed, this is a form of the very polymorphous south-western *Quercus undulata*. It is a plant with cordate, mostly entire leaves, and nearly identical leaves can be found on plants growing on the cliffs above the cañon of the Arkansas River, in Colorado, which produce, among leaves of several different shapes, the undulate-dentate leaves of Torrey's type of *Quercus undulata*.

Quercus undulata, which can always be recognized by the blue color of its foliage from the green-leaved Rocky Mountain White Oak, *Quercus Gambelii*, with which it has often been confounded, is distributed from the cañon of the Arkansas River, in Colorado, to western Texas and through New Mexico and Arizona to southern Utah and Nevada and to northern Mexico. Usually shrubby, it was found last summer by Professor Toumey growing into a small bushy tree in some of the sheltered cañons of the mountain ranges of south-eastern Arizona. It is a form of this species with small entire or spinescent leaves (*Quercus pungens* of Liebmamn), often clothed on the lower surface with fulvous pubescence, that covers the mountains of central Arizona, south of the Colorado plateau, with vast thickets six or eight feet high, from which cattle and sheep obtain the best fodder furnished by this region.

A good deal of confusion with regard to our south-western Oaks has been caused by the mistaken reference of one of the New Mexican and Arizona White Oaks to Liebmamn's *Quercus grisea*. This Arizona tree (*Quercus undulata*, var. *grisea*, Engelmann, Whipple's Rep., vi., 250) is one of the largest and commonest Oak-trees of the south-west, and is found scattered over all the mountain ranges south of the Colorado plateau above elevations of about five thousand feet; it has oblong or obovate, entire or irregularly dentate, mostly cordate, narrow leaves, strongly reticulate on the lower surface, which, like the branches, is covered with yellow pubescence. The leaves vary much in width. Last spring I found at Fort Huachuca, in Arizona, trees of this Oak mostly covered with leaves of the ordinary form which bore individual leaves on fertile branches that were broadly obovate, and not distinguishable in shape and size from those of *Quercus reticulata*, a species with long-stalked, spicate fruit, of which, at first sight, this tree might be considered an extreme form, especially as its leaves resemble those of that species in their pubescent covering and prominent reticulate veinlets, but these trees differ in the character of the bark, in the length of the peduncles, which on *Quercus reticulata* are often five or six inches long, in the size and shape of the fruit, in the thickness of the cup-scales and in the cotyledons; these are purple and very astringent in both species, but in the former are united into a solid mass like those of *Quercus oblongifolia* and of the Live Oak of the southern states. As this species is without a name, I propose to call it *Quercus Arizonica*,† as it is

* *Quercus Toumeyi*, n. sp. Leaves ovate or ovate-oblong, rounded or cordate at the base, acute and apiculate at the apex, entire or remotely spinose-dentate, reticulate-venulose, persistent. Flowers unknown. Fruit sessile; nut oval or ovate, acute, glabrous on the inner surface; abortive ovules basal; cup thin, shallow, cup-shaped or turbinate, the scales ovate, thin, regularly and closely imbricated, tomentose on the back, produced into short free tips rounded at the broad apex.

† *Quercus Arizonica*.

Quercus Emoryi, Watson, Wheeler's Rep., 17 (not Torrey) (1874).

Quercus undulata, var. *grisea*, Engelmann, Rothrock Wheeler's Rep., vi., 250 (not *Quercus grisea*, Liebmamn) (1878).—Greene, Western American Oaks, 50 (in part), t. 14. *Quercus grisea*, Sargent, Forest Trees N. Am., Tenth Census U. S., ix., 144 (excl. syn.) (not Liebmamn) (1884).

one of the largest and most abundant trees in the southern part of Arizona, where it was discovered in 1871 by the party of United States explorers under command of Lieutenant George M. Whipple. *Quercus reticulata* in Arizona and New Mexico is confined to the summits and high cañons of a few of the highest mountain ranges, where, as a low shrub or small tree, it leads a precarious existence, while *Quercus Arizonica* is a large tree, the trunk sometimes four feet in diameter, growing from the upper margin of the mesas to the mountain-tops. In characters it is nearly intermediate between *Quercus reticulata* and *Quercus oblongifolia*, resembling the latter in its purple connate cotyledons, but differing from it in its thicker bark, pubescent branchlets, thicker, rigid, pubescent, oblong leaves, in its larger fruit and thicker cup-scales. It is a tree, too, of higher elevations than *Quercus oblongifolia*, which rarely ascends above five thousand feet, covering, with *Quercus Emoryi*, the upper part of the mesas, especially where mountain cañons open to the plain, and below the principal growth of *Quercus Arizonica*.

QUERCUS DUMOSA.—Of all North American Oaks this species of California is the most variable in the shape of its leaves. The ordinary form of the coast-ranges in the southern part of the state is a low shrub with oblong leaves, rounded or acute at the apex, with sinuate or spinose-toothed or entire, or slightly lobed margins, and usually about three-quarters of an inch long and half an inch wide, with short petioles and coarsely reticulate veinlets; but in sheltered cañons, on some of the islands off the California coast, a few individual plants attain the size and habit of trees, and produce large, deeply lobed leaves not very unlike those of the eastern White Oak. This is the *Quercus MacDonaldii* of Greene; and no one, from the mere examination of herbarium specimens taken from one of these trees, could imagine that they belonged to *Quercus dumosa*. When the trees are seen in their native thickets, however, it becomes apparent that they are only more vigorous individuals of a species which is represented in the same thicket by individuals with small and entire or spinescent or slightly lobed leaves. In these island cañons the same individual bears entire, spinescent, or rarely lobed, large or small leaves on the same or on different branches; and vigorous shoots on plants with otherwise small entire or spinescent leaves often produce large deeply lobed leaves five or six inches long. Seen from a little distance these large-leaved individuals cannot be distinguished by their habit, color and general appearance from their associates. North of San Francisco Bay the prevailing form of *Quercus dumosa* is distinguished by its rounder, thicker and paler leaves, which are concave on the upper, and strongly revolute on the lower, surface, with entire or spinescent margins. This very distinct variety was called by Engelmann *Quercus dumosa*, var. *bullata*, but as *bullata* had been used before as a varietal name of another species of *Quercus*, I shall substitute for it *revoluta*, and call this variety *Quercus dumosa*, var. *revoluta*.

QUERCUS DURANDII.—This White Oak of central Alabama and Mississippi, of central and western Texas and northeastern Mexico, was discovered in 1850 in western Texas by the botanists of the United States and Mexican Boundary Survey, and was first described by Torrey in the botanical report of the commission, published in 1858, as *Quercus obtusifolia*, var. *brevilobata*. The next year it was found by Mr. S. B. Buckley in central Alabama, and in 1860 was described by him in the Proceedings of the Philadelphia Academy as *Quercus Durandii*, but Torrey's name is older than Buckley's, and so will have to be adopted, and as *Quercus obtusifolia* (perhaps a misprint for *obtusiloba*) had been used before Torrey applied it to this species, Torrey's varietal name is taken up, and this handsome and distinct southern White Oak will appear in *The Silva of North America* as *Quercus brevilobata*, a name which, fortunately, pretty accurately describes the form of its leaves.

QUERCUS MUEHLENBERGII.—The oldest varietal name of this species, *Quercus Prinus acuminata* of Michaux, pub-

lished in 1801, was passed over by Engelmann when he raised this variety to a species because there was a *Quercus acuminata* published by Roxburgh in 1832. Michaux's varietal name, however, being older than Roxburgh's specific name, it must be taken up under the rules of nomenclature adopted by American botanists. *Quercus nana* must replace *Quercus ilicifolia*, which was first described by Humphrey Marshall in 1785 as *Quercus rubra nana*, a fact pointed out as long ago as 1801 by Willdenow & Muehlenberg in their paper on American Oaks in the third volume of the *Neue Schriften Gesell. Nat. Fr. Berlin*. And finally, in raising Chapman's *Quercus obtusifolia*, var. *parvifolia*, from western Florida, to the rank of a species, I find that *parvifolia* was used a year earlier by Alphonse de Candolle as the name of a variety of another Oak, so it is not available for this species, which I wish to call *Quercus Chapmani*, in honor of the author of *The Flora of the Southern United States*, who first distinguished it.

Foreign Correspondence.

London Letter.

THE WEATHER.—Severe frost has been experienced in England since January 23d. The temperature at Kew has been below freezing-point since the 25th—that is, for three weeks, and from February 6th to 13th the minimum temperature on the ground ranged from seven degrees to zero, the maximum in the screen in the same period ranging from twenty-three to thirty degrees. This is very exceptional, nothing approaching it having been known here since the time of the Crimean war (1856). The Thames is frozen over at Kingston; a coach and four have been driven across the Serpentine in Hyde Park; there is a water famine in many districts in consequence of the freezing of the water-mains, the frost having penetrated into the ground to a depth of two feet. Following an exceptionally mild November and December this severe cold is certain to do an enormous amount of injury to garden-plants. The rise in the price of vegetables, including potatoes, has been great, and it is probable that garden produce generally will be at a high premium when the thaw comes.

THE ROYAL HORTICULTURAL SOCIETY held its annual general meeting on February 12th. Sir Trevor Lawrence, the President, drew attention to the principal features in the report, which records, among other things, that twenty-two exhibitions had been held; that one hundred and seventy-eight first-class certificates and three hundred and seventy-one awards of merit had been adjudged by the several committees to as many plants, fruits and vegetables; that the experimental and trial work in the garden at Chiswick, under the superintendence of Mr. Barron, had been of an important character, many new varieties of Cauliflowers, Peas, Potatoes, Tomatoes and Strawberries having been cultivated and examined by experts; also of Carnations, Picotees, Cannas, Clematis, Campanulas and other popular garden flowers. The examination in the principles and practice of horticulture, held on May 1st, had resulted in 126 candidates presenting themselves, nearly one hundred of whom passed, two having won scholarships worth £39 a year each.

A committee has been appointed to draw up a code of rules and regulations for judging at fruit and flower shows. The Scientific Committee, composed of eminent men of science, invite all interested in horticulture to submit to them cases of diseased, injured or abnormal plants of all kinds, and offer to give advice in respect to the prevention or cure of disease. The income of the society for 1894 amounted to £5,550, and the expenditure to a little over £5,000. The present condition of the society is on the whole most satisfactory. The want of a suitable home and exhibition hall for the society is still felt, and the further development of Chiswick as a representative school of horticulture and experimental ground for English horticulture is generally hoped for by those who know the value

such an establishment would have in the promotion of horticulture. Botany and scientific gardening are looked after at Kew, but there is much need of a national fruit and vegetable garden such as Chiswick might be.

PHALÆNOPSIS YOUNGIANUM.—A fine spike of flowers of this handsome, large-flowered Orchid was shown on Tuesday by Baron Schröder, and was awarded a first-class certificate. It is said to be a natural hybrid between *Phalænopsis Aphrodite* (*amabilis*) and *P. Stuartiana*, Messrs. Veitch & Sons having imported it accidentally a year or so ago among a batch of the last-named species. The spike shown by Baron Schröder bore ten flowers, each nearly three inches across, or as large and full as a good form of *P. Aphrodite* (*amabilis*), the color being blush-white, with the lower sepals and front lobe of the lip spotted with red-brown, and the side lobes of the lip striped with crimson. It was first flowered in February last year by a Mr. G. Young, and then obtained an award of merit.

PHALÆNOPSIS INTERMEDIA PORTEI.—The largest flower-spike

being wholly of a deep, glowing maroon-crimson, the lip darker than the rest of the flower. This is an *Orchid* of quite exceptional merit, *Calanthes* of this section being as easy to grow and flower as any *Orchids*, and they flower at a time when they are especially valuable. We have many good varieties and hybrids among *Calanthes* now, but this is much better than any of them. There is something to be said in favor of hybridizing *Orchids* when a plant like this *Calanthe* is the outcome.

CYMBIDIUM EBURNET-LOWIANUM var. *SUPERBUM*.—This is an improvement on the hybrid whose parents are indicated in the name, and which was raised and flowered by Messrs. Veitch & Sons in 1889. The variety has larger, better-formed flowers, which are also clearer in color, being cream-yellow flushed with rose, with a blotch of crimson on the front lobe of the lip. The habit of the plant and form of the flowers resemble *C. eburneum*. The plant which was shown by Messrs. Veitch & Sons on Tuesday last had a spike eighteen inches long, bearing four flowers,

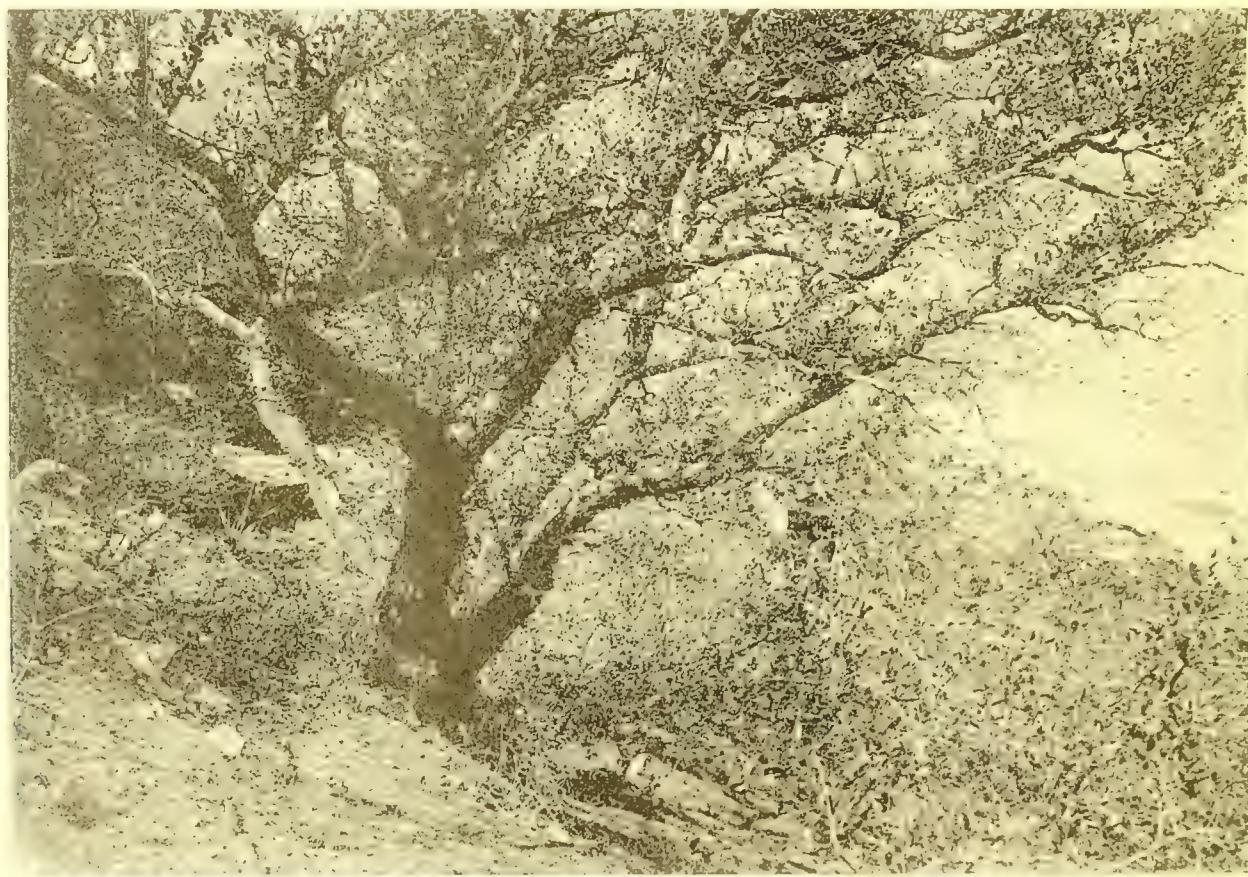

Fig. 13.—*Quercus Toumeyi*, n. sp.—See page 92.

I have ever seen of this plant was shown last Tuesday by Lord Rothschild Tring, and obtained a first-class certificate. It was two feet long, with five branches each, from six to nine inches long, and it bore forty flowers each about two inches in diameter and colored white, with a tinge of purple at the base of each segment, the lip being yellow, amethyst-purple and red. This variety was introduced in 1861 by a Frenchman named Porte, and first flowered in the collection of Messrs. H. Low & Co. It is the best of the several forms known of *P. intermedia*.

CALANTHE BARON SCHREDER is the most beautiful of all *Calanthes*. I noted it in one of my letters about this time last year, when it was shown by Baron Schröder, in whose garden it had been raised from *C. vestita oculata*, crossed with *C. Regnieri*, and it obtained a first-class certificate. The baron showed a flower-spike of it again last Tuesday; it was three feet in length, carried twenty-five perfect flowers, each two inches across, in form equal to the very best of *C. vestita*, and in color absolutely beyond comparison,

each four inches across. It was awarded a first-class certificate. Mr. Veitch informed me that this variety was raised from seeds out of the same pod as produced the type flowered in 1889. The latter I called poorer than either parent, but the variety is a good acquisition.

ODONTOGLOSSUM CORONARIUM is a noble *Orchid*, but somewhat difficult to flower. Last Tuesday two large flower-spikes of it were shown, one from the garden of Sir Trevor Lawrence, the other from Baron Schröder. The latter bore twenty-five flowers and was deservedly awarded cultural commendation. The plant thrives in the coolest and moistest house, and it appears to delight in as much moisture at the roots as a *Disa*. It has a stout, long rhizome, bearing large ovoid pseudo-bulbs three inches or more apart, and leathery leaves ten inches long. The spike is erect, about a foot long and generally crowded with flowers, as in a *Hyacinth*. Each flower is two inches across, with equal spreading oblong fleshy segments colored coppery red, with a yellow margin and a few yellow spots at the base, the lip being

wholly yellow, except at the base. The whole surface of the flower shines as if it had been coated with varnish. It should be planted in sphagnum and peat in a shallow teak basket or raft and suspended near the roof glass in a shady position in the cool house.

HYBRID CYPRIPEDIUMS.—A list, presumably complete up to

may see fit to grumble at the creation of such a host of what I call pedigree Orchids, and however poor we may vote many of them to be as decorative plants, they continue to excite a considerable amount of interest among a section, at any rate, of Orchid growers, for whom Mr. Chapman's list will have great value. Viewed as a record of work done by the hybridist, this list in itself is astonishing, while in the extreme divergence of character in the parents of some of the hybrids raised the systematic botanist has food for reflection.

FLOWER DRYING.—A collection of dried flowers of Orchids was an interesting exhibit last Tuesday. They had been prepared by Mr. Chapman, gardener to Mr. Measures, and they comprised Cypripediums, Cattleyas, Sophronitis, Lælias and similar popular brightly colored Orchids. The merit of the exhibit lay in the wonderful preservation of the colors, which were quite as brilliant as when the flowers were alive and looked, a short distance off, like accurately colored drawings. Mr. Chapman succeeds in preserving the colors by putting the flowers between sheets of blotting paper under sufficient pressure to prevent them from shriveling, and then placing them in a hot oven. The flowers thus treated are thoroughly dried in a few hours without any loss of color. When mounted on paper and exposed to light and air the colors in time lose a little of their brilliancy, but flowers that had been done a year had not appreciably faded. The difficulty is to fix the colors so that they will not fade. Mr. Chapman's method is likely to be of greater value to horticulturists than botanists.

INTERCHANGE OF SEEDS.—The botanical gardens of importance in Continental countries and the United Kingdom annually print and circulate each a catalogue of the seeds available for distribution from those ripened in the gardens, and also, in some cases, including surplus seeds obtained from tropical countries. These catalogues are, as a rule, posted to all botanical establishments so that selections can be made. In this way it is easy to replace losses among plants of botanical interest only, and especially of annuals and other easily lost plants which may fail to ripen in some gardens, but succeed in others. The custom is an excellent one. I know that at Kew it is found to be of considerable help toward maintaining the collections, and also that Kew contributes largely to the maintenance of collections in other gardens, as is shown by the fact that the number of packets of seeds ripened at Kew and distributed last year amounted to 5,200. This does not include the seeds received at Kew and redistributed to the colonies, etc. Is there such an interchange of seeds among the botanical gardens of the United States?

1. A fruiting branch, natural size. 2. Cup-scales, enlarged. 3. A nut, natural size.
4. A seed, natural size. 5. Leaves, natural size.

the time of publication, of all hybrid Cypripediums, has been drawn up by Mr. H. J. Chapman, gardener to Mr. R. I. Measures, of Camberwell, whose collection of Cypripediums is the largest known. Mr. Chapman's list is published in *The Gardeners' Chronicle* this week. It comprises no less than five hundred and twenty-two hybrids. The parents in each case are given, and also the raiser's name. It must be acknowledged that however much some of us

Plant Notes.

HOUSTONIA CÖRULEA.—This charming, although diminutive, native plant is rarely cultivated, although not at all difficult to propagate and preserve. Where it is not indigenous, it is always an attractive novelty when in flower, and where it does grow wild it might profitably receive more attention than it generally gets. Where the plants grow

naturally they can be transplanted into gardens, frames or pots, and with ordinary care they will continue to thrive year after year. They will grow well in almost any good soil, one composed of sand and loam being apparently most congenial, and they luxuriate where they get plenty of moisture in the growing season, but are not too wet. They may often be found in great profusion on rocky hills near the seashore, where there is very little soil, but plenty of moisture from frequent mists or fogs, and where few larger plants get a foothold and overshade them. When potted and kept in a cold frame they can be forced into a profusion of bloom in midwinter, when the delicate beauty of the flowers is happily displayed above a low, close mat of green foliage. The flowering stems are rarely more than three or four inches long, and bear tiny yellow-centred, four-petaled flowers, which vary from almost pure white to a rosy lilac or light blue on different individuals. To the botanist these blossoms possess a peculiar interest on account of the fact that they are dimorphous, being of two forms of structure, some flowers having protruding stamens and short styles, and others having the stamens included within the tubes, while the styles are long and the stigmas exserted. This little Houstonia, sometimes called Bluets and Innocence, among other local popular names, being a perennial, will in time form quite a broad tuft by spreading from a single stem by slender thread-like root-stocks or creeping stems. The plants can be propagated by seeds or by division of the delicate masses of roots, which must then be carefully grown until they again form good independent tufts.

Nymphaea O'MARANA.—This is a hybrid between *Nymphaea dentata* and *N. Sturtevantii*, raised by Mr. Peter Bisset, gardener to G. G. Hubbard, Esq., Twin Oaks, Washington, D. C., and now in flower in the glass-covered tank of Mr. John McElvery, which was described in our issue for January 9th. Indeed, it has been blooming every day since early in September, and it is constantly showing new buds, being more floriferous than *N. Devoniensis* at this season, and not excelled by any Water-lily in persistent and continuous bloom. This is particularly remarkable from the fact that the plant is growing in a pot only ten inches in diameter. After having passed through the shortest days of the year it seems now as vigorous as most *Nymphaeas* do in July. Its large metallic green leaves resemble those of *N. dentata*, being strongly toothed at the margin, but they have a wider cleft. The full flowers are shaped like those of the same parent, are borne on stout petioles which lift them well above the water, and they measure eight or nine inches across. The color is a beautiful glowing pink, without any of the shading of magenta which is seen in *N. Devonensis*. The stamens are of an orange color, with the marked incurved form which shows the blood of *N. Sturtevantii*, and they tint the petals with a beautiful reflection. The flower is rather lighter than that of *N. Sturtevantii*, but, unlike most other pink Water-lilies, they grow darker with age, instead of fading out.

BEGONIAS PRESIDENT CARNOT and *B. FRANÇOIS GAULIN* are among the showiest and most effective winter-blooming shrubby Begonias. They are French hybrids produced by Monsieur Crozy, and are crosses of *B. rubra* with probably *B. Olbia*. They resemble *B. rubra* in habit, well-grown plants forming strong, straight shoots with flowering side branches. The foliage is distinct from either of the parent species, being oblique, smooth-veined, large, light green above, and sometimes suffused with red below and on the edges. The plants produce freely well-furnished racemes of large flowers, some two inches long, and mostly female. There is a difference in the coloring of the two hybrids, the latter being the lightest. The coloring is not as pure in tone as that of *B. rubra*, having a somewhat bluish cast in the pink of its flowers. Plants are easily propagated, and cuttings struck now will make strong plants for next winter. *B. François Gaulin* was figured in *GARDEN AND FOREST* (vol. vi., page 123), but the raceme there shown was smaller than those on well-grown plants.

BOMAREA CARDERI.—*Bomareas* are somewhat rare plants in this country, although they were grown in English gardens nearly twenty years ago, and have been known more than fifty years in botanical collections. They belong to the Amaryllidæ, being closely related to the Alstroemerias, but they have long, slender, twining stems with bright green leaves, and bear flowers in terminal umbels. A plant of *B. Carderi* in a private house near this city is now in bloom, and, indeed, it has been in bloom since midsummer, and its flowers are almost as large as those of a *Lapageria*. The color of the flower is a rich rose, with conspicuous brown spots near the tips of the outer segment, and larger purplish spots on the inner segments, which are greenish white. In large plants the umbel will contain forty of these flowers, and will measure as much as two feet or two and a half feet across. The roots produce fleshy tubers, but they have no buds, and, therefore, are not useful in propagation. They are multiplied by the means of seeds or by dividing the root-stalks in the spring. They seem to do best in a well-drained border in a warm sunny greenhouse. The stems of *B. Carderi* often grow to a length of ten or twelve feet, and being covered with broad, ovate, bright green leaves, they are striking plants, and commend themselves as suitable for every considerable greenhouse collection.

Cultural Department.

Grapes in North-eastern Vermont.

IT was in 1867 that I planted my first Grape-vines on the shore of Lake Memphremagog; the first, I think, that were ever planted there. Hartford Prolific was the variety, and the only one I had any hope of even partially ripening. It is the shortness of the season alone which forbids grape-growing in this locality. Otherwise, it is an ideal spot for the purpose. Fog is unknown, and dull days unfrequent; but frost comes in September, and it sometimes does not wait many days after the end of August. There are exceptional years, perhaps one in six, when frost holds off much longer; but the Grape we want is one which will be ready to cut by the tenth of September.

The orchard on my old place, but a few rods from the east shore of the lake, is very well protected from light frosts; but until near the first of June, and sometimes as late as the tenth, we are liable to have a killing frost. This, however, is not common, having occurred but thrice in twenty-five years. My Grape-vines are on a light trellis, in front of a high and tight fence, eight hundred feet long and facing south; stakes are also used, and the summer pruning is less severe than is usual in commercial vineyards, as I am not growing for market; and handsome clusters not being imperative, while protection from frost or chill is, I do but a moderate amount of pinching. The result is, not so many handsome clusters, but more ripe ones.

As to varieties, I have invested in every new early sort as it has come out, so that I have a much larger assortment than I should plant if I were to begin afresh. Hartford Prolific has been quite discarded, not only for shelling, but because it is too poor in quality. Eumelau has also been dropped, though only lately, to give place to more promising sorts. In fact, none of Dr. Grant's seedlings have proved very useful. Salem is the only one of the Rogers hybrids. It ripens so as to be eatable in about half the seasons. Isabella is too late, though it has sometimes ripened quite nicely. Delaware gets fairly sweet in most years, and is regarded as the best of the older sorts. In a hot summer Brighton ripens perfectly; but in a steadily cool one it will not ripen at all, while the vine is very apt to die after such a season. Moore's Early colors, but very rarely gets sweet. It is, however, a good culinary sort, especially for jelly.

I had got pretty fully convinced that this was as far as we should ever get in grape-growing in northern Vermont, when, at the meeting of the American Pomological Society at Boston, in 1887, my eyes lighted upon specimens of the "Green Mountain," dead ripe, when not a single other variety on exhibition was eatable. Here was a grape which I felt sure would ripen every year on Lake Memphremagog; and it does so. Since then I have fruited the Diamond, and find that it is but very little behind the Green Mountain in season; while I cannot see why it will not prove a good commercial variety, which Green Mountain never can be, on account of the feeble adhe-

sion of the fruit to the stem. After such successes I am beginning to think that even in the cold north we may be able to make commercial grape-growing at least moderately successful. It is most gratifying, after so much failure, and with so little expectation or reason for hope, that such a measure of success has been reached. And we may do better yet, for the Wild Grape is native here, draping the trees by the river banks. The name first of all given to New England points to a future when it will be truly a land of Vines.

Newport, Vt.

T. H. Hoskins.

Cinerarias.

LIKE many other old-time favorites, these flowers have been left somewhat in the background, although few, if any, greenhouse plants supply us with such a variety and brilliancy of color. In England they are more largely grown, and every year witnesses some improvement in Cinerarias, either in habit of growth, form of flower, or variety of color. The cooler English climate during the growing season is more suitable to the growth of these plants than ours, and this may partially account for their greater popularity across the sea. They can sow seed much earlier, and this allows a longer season of growth, with firmer, more mature and more stocky plants. Still, we have the advantage of brighter weather and a drier atmosphere during the winter months, and with a little study of the required temperature there is no reason why we should not grow them equally as well. The first of August is early enough to sow the seeds; they germinate readily with ordinary care and should be pricked out into boxes as soon as they are fit to handle. A cold frame facing north, with slight shade from strong sunlight, will be found most suitable for them at this stage, and they should be potted on as they attain size, first into three-inch pots, and finally into eight-inch pots, a light but moderately rich soil being used all along. A plentiful supply of water, but no stagnation, is essential. The most troublesome insect enemy is green fly, which can be destroyed either by smoking, dusting with tobacco powder, or dipping in a weak solution of any ordinary insecticide. For winter quarters a house where they can be kept well up to the glass, and where a temperature of sixty degrees by day and forty degrees by night can be maintained, will suit them well. All flower-buds should be pinched off as they appear until about the first of January, after which time pinching should be discontinued, and this will bring them in good time for Easter. When the pots are well-filled with roots they will be greatly benefited by occasional applications of liquid-manure. Nothing is more suitable for this purpose than water from the cow-sheds, which, however, should be well diluted.

William Scott.

Tarrytown, N. Y.

Nelumbiums.

THE Nelumbiums have no rivals among aquatic plants for stateliness, and they can be used not only in the large lakes and water-basins of public and private parks, but they have a refined character which makes them appropriate even for small water-gardens. They are so perfectly hardy that it is difficult to understand the frequent complaints that they are difficult to grow and establish. One cause of failure may be that they are planted too early. Planting should be delayed until warm weather and genial conditions set in, so that the tubers or plants will make active growth at once. When tubers are received from a distance they may have been subjected to a warm temperature in shipment, and, therefore, the chill of a plunge in cold water may check their vital energies. Where the tubers have made young rootlets it is much safer to plant them in shallow boxes and keep them protected either in a cool greenhouse, pit or frame until it is safe to place them in permanent quarters. By all means avoid the check to growth, which always means weakness, if not actual death, to the plants.

Another good plan is to place such roots in large pots or pans and keep them growing until warm weather, when the plants can be turned out with a good ball of soil and roots and carefully deposited where they are to bloom. Where there are no tanks for the reception of large pots, tubs can be used. Another method is to start seeds. Of all seeds none germinate more readily than those of Nelumbiums, provided the hard shell is filed through at the base of the seed so that water can penetrate. The plumule escapes first, sometimes two or three days before a rootlet is visible, and always from the base; therefore, by filing at this particular spot much assistance is given to the young seedlings. In a temperature of seventy-five degrees the seed will germinate in about six days, sometimes less. The seeds may be placed singly in small

pots, or may be started in water and potted afterward; in either case the young plants must be grown and established in large pots or pans before planting permanently. Nelumbiums will not flower the first year as seedlings, but will, in most cases, do so the second or the following year. Apart from their flowers, the Nelumbiums are highly ornamental plants and worthy of cultivation for their foliage alone.

Clifton, N. J.

W. Tricker.

[Two seeds of *Nelumbium* were placed in a small bottle of water and set on a desk in this office, and they germinated within a week.—ED.]

A Few Annuals.

THERE seems to be a perennial demand for information about annuals, not only from beginners in gardening, but from those who are more or less familiar with flowers, but do not care to experiment—persons content to wait till they find a good thing mentioned. Last year I made full notes of the more important annuals and a few other useful flowers which can be readily grown from seed in one season. It may be of some use now to furnish notes of other annuals which may be considered of secondary interest. By secondary interest I mean not that these flowers are less beautiful than the first mentioned, but they are not those one would usually select for a limited list. Often they are perfect as border flowers, but lack either the stability or grace of form which is required in flowers useful for cutting. For instance, nothing is more beautiful in a large border than a mass of the *Eschscholtzia*, with its finely cut glaucous leaves and its brilliant yellow flowers of various shades, borne so freely, yet it may be considered of secondary importance, as these flowers are quite fugacious. It must be, of course, understood that, in recommending, one is influenced more or less by his prejudices or feelings. A writer in *GARDEN AND FOREST* lately suggested that I was influenced in the choice of varieties of a flower by sentiment. The accusation was partly correct, and I am convinced that if an amateur does not grow plants and sentiment in his garden in about equal proportion he is not getting the full benefit of his labor. The most satisfactory flowers are those, however common, from which one gains inspirations of beauty and to which some pleasant associations are attached.

As for the cultivation of these quick-flowering plants, we are apt to plant the seeds too early, either in the greenhouse, or, lacking this, in some spare corner of the dwelling, and in either place they become a burden and are never as strong and vigorous as those grown with more air and exposure. In gardens managed in a comfortable, leisurely way, and well furnished with a good assortment of plants, the planting of seeds of annual flowers may be delayed till they can be sown in an outside frame, where they will progress without check and make strong plants, quite early enough. When the night temperature ranges about 50 degrees, F., is the proper time. This will usually be toward the end of April here. In this procedure we have the spring-sown annuals commencing to flower just after the June Roses. In the early year we have flowers in abundance from the bulbs, the flowering shrubs, and the early-flowering herbaceous plants. The fall-sown Poppies and *Centaureas* will cover the ripening foliage of the bulbs and lead the flowering of those annuals which will naturally fill the gap as the hardy Roses pass away. It is difficult to forward many of the annuals much, and the trouble of early care under shelter is scarcely warranted.

The list of annuals, or plants to be treated as such, given last year, included as most usually desirable China Aster, *Calliopsis*, *Calendulas*, Marguerite Carnations, *Cosmos*, *Centaureas*, *Chrysanthemum coronarium*, Indian Pinks, *Gaillardias*, Sunflowers, African and French Marigolds, *Mignonette*, *Nasturtiums*, *Pansies*, Poppies, Sweet Peas, *Torenia* and *Zinnias*.

This list takes no account of vines and a number of hardy annuals, many of which are interesting and worth growing. Among the many remaining annuals of the seed lists, not climbers, the following seem the most desirable: Sweet Alyssum, Balsams, Candytuft, *Eschscholtzias*, Swan River Daisies, Chrysanthemums (single annual), Larkspurs, Marvel of Peru, *Nicotiana affinis*, Petunias, *Phlox Drummondii*, *Portulaca*, *Salpiglossis*, *Spheroxyne*, Stocks, *Venidium Calendulaceum*.

This list, it will be seen, includes some of the most important items of the seedsmen's stock and some flowers considered indispensable by many growers, but the two lists are offered as a fair guide to those whose experience is, perhaps, a blank. These plants are so familiar in old gardens that the seedsman usually dismisses them with a few lines. I hope to add a little to the perspective by briefly noting their beauties and shortcomings, with a slight account of the climbers.

The Cultivation of Tea in America.

To the Editor of GARDEN AND FOREST:

Sir.—In Mr. Watson's London letter, in your issue of January 16th, I notice some remarks on Tea cultivation which might induce American planters to think that the plant could be profitably cultivated in the southern states. It will, no doubt, grow there and may produce tea of fair quality, but unless labor can be had at an almost nominal rate it cannot compete in price with tea from India, Ceylon and China. A great deal of the manufacturing process is now done in India and Ceylon by machinery at a low cost, but hoeing and picking must be done by hand, and as in Sikkim we pay coolies at the rate of from four to seven rupees a month, without food, which is equal at the present rate of exchange to from one to two dollars a month, and have virgin soil of the greatest fertility, in a most forcing climate, at a trifling cost, we have advantages in India which seem to me to make competition in other countries impossible. Statistics show that the proportion of China tea now used in England has steadily fallen, notwithstanding its very low price. The average price of Indian tea in Calcutta on January 24th was nine annas, equal to about fifteen cents a pound; and though this includes much tea of low quality, yet an average of ten annas is a very profitable price for the total output on many plantations, and some pay fairly with an average price of only six annas.

I was much surprised when in America to find how little known Indian Tea is there, and how few people really know the taste of good tea. If it were understood that almost every leaf of Chinese tea is contaminated by perspiration, owing to the system of rolling by hand still followed there, while Indian tea is now almost everywhere rolled by machinery, I feel sure more people would drink the India product. Adulteration is absolutely unknown in India, while much China and Japan tea is artificially colored. Of the various sorts of Indian tea, Darjeeling is the finest for drinking unmixed. Assam and Cachar tea is stronger, and the best of it too astringent for many palates. Ceylon is good cheap tea, but rarely has the delicate aroma of Darjeeling, Pekoe or Broken Pekoe. The presence of a number of the young unopened leaf-buds, technically called tips, in Indian Tea, is always a sign of good quality, and in the finest qualities of Darjeeling tea there is a delicate after-taste of chocolate, more easily perceived when the tea is drunk half cold. Weak cold tea is about the best and most refreshing drink I know in hot, dry climates, and much less heating than coffee, which is also more difficult to make properly.

Cheltenham, England.

Flowering House-plants for Early Winter.

To the Editor of GARDEN AND FOREST:

Sir.—Owing to certain mischances, the last autumn found us with only a few large plants for winter display, and these were mostly so-called foliage plants. We wanted something bright in the way of flowers during November and December. We had quantities of potted plants, but their lack of size and dignity emphasized the need of something with more character and distinction. Later on we could have Azaleas, Lilies, Genistas and Holland bulbs, but for these two months we had no decorative flowering plants except Chrysanthemums. In early autumn we had a three-days' rain that soaked the beds to the bottom, and as frost approached I thought of the bright Salviyas and royal Dahlias that would soon be frozen and blackened. Why not try these for window-plants? One deep stroke with mattock behind the ball of roots, then one on each side, then a deft understroke and a steady leverage from the mattock, and Salviyas three feet in diameter, Celosias with heads sixteen inches long, clumps of Crozy Cannas and great bushes of Cosmos came up with huge balls of earth unbroken. Placed in tubs the lifted plants were shaded for a day or two, but this precaution seemed unnecessary. Not a leaf withered or a flower drooped. The gorgeous Cockscombs and flaming spikes of Salvia made a bright display for three months, while the smaller and later plants had a chance to do their growing and make ready to take their place later on.

These garden-grown plants had double the bulk and weight of roots that would have been made by a pot-grown plant. But to offset this disadvantage they had an exuberance quite unusual to indoor plants, and, altogether, the experiment was so successful that I shall certainly try it another year.

Pineville, Mo.

Lora S. La Mance.

Notes from Wellesley, Massachusetts, and its Vicinity.

To the Editor of GARDEN AND FOREST:

Sir.—On the occasion of a late visit to Mr. Joseph Tailby, of Wellesley, noted as the introducer of Grace Wilder and other good Carnations, we found that the Mrs. Fisher, as grown here, is superb. The centre bed of one long house, planted with this variety, was a sheet of snowy bloom, and the individual flowers showed little of the tendency to burst their calyces, an objection which is sometimes urged against this plant when it is grown in the winter, and there can be no doubt that where it does well it is still the leading white Carnation. Mr. Tailby's plants are the best I ever saw, and worthy of a long journey to see. Of the seedlings here, Henrietta Sargent, the new yellow, and Helen Schaffer, white, are two of the best. William Scott is the leading pink variety, but Ada Byron appears to be a failure.

A small bench of the new Farquhar Violet looked promising, while Lady Hume Campbell and other standard varieties were recovering from an attack of leaf curl and flowering finely. At the Wellesley College greenhouses two beautiful specimens of *Acacia pubescens*, with stems seven feet long, were in flower, and their drooping branches, thickly hung with racemes of sulphur-colored flowers, testify to what was said in a recent number of GARDEN AND FOREST as to the value of this Acacia for winter flowering. There are few Orchids here, but all are well grown, and two plants of *Dendrobium nobile* were seen which can hardly be duplicated elsewhere in the United States. One of these specimens usually finds its way to the spring exhibition of the Massachusetts Horticultural Society, and is always a centre of attraction there. The twin plants are now carrying from six hundred to a thousand buds each. The sweet-scented *Pilumna nobilis* and *Angraecum superbum* were both nicely in bloom, and a fine lot of *Odontoglossum* were very interesting. At Mr. Hunnewell's place the plant of *Clematis indivisa*, which has been described in your columns, covers a large part of the roof of one of the cool houses, and it is now a picture, thousands of its beautiful white flowers being fully expanded. For covering pillars and training thinly over the roof of a greenhouse, nothing is more desirable than this plant. It will flower freely in a six or eight-inch pot, but to see it in perfection it should have the treatment which Mr. Harris gives it here, where it is planted out and occasionally root-pruned to keep it within bounds. I noticed fine flowers of *Phalaenopsis* in the warm Orchid house, but most of the Cattleyas, Dendrobiums and other Orchids are held back so that they can flower with the Rhododendrons, at which season Wellesley is at its brightest. At Mr. Walter Hunnewell's I observed a fine display of the best winter-flowering Begonias, and was interested in Mr. Hatfield's specimen *Chrysanthemum* plants, which were already in four-inch pots. Here the Violet, Lady Hume Campbell, looked clean and healthy and was behaving properly, as it was at Mr. Arthur Hunnewell's place.

At Mrs. B. P. Cheney's, South Natick, Mr. John Barr, the head-gardener, showed me a Rose house which contained flowering plants of Madame de Watteville, Catharine Mermet, Bride, Bridesmaid and Perle de Jardin, which were as good as can be seen anywhere. Cyclamen here in ten and twelve inch pots, Cinerarias and Carnations are all capitally done. In the graperies I observed by the mulching on the border that the vines here received generous treatment, and it is worth stating that in too many places the failure of fruit is owing to starvation, the vines neither receiving a proper amount of food or of drink. At the greenhouses of Mr. David Nevins, in South Framingham, I saw those remarkable Violets which have made such a sensation at two recent exhibitions in Boston. The average flowers were as large as a half-dollar, and exceptional ones will cover a silver dollar comfortably. The variety chiefly grown is Marie Louise, but Swanley White is equally good. The plants are grown in eight-inch pots in a Carnation house temperature, and many of them show three dozen, and even more, fully expanded flowers, with any number more coming on and not a sign of spot or leaf curl. Mr. McKay, the grower of these remarkable flowers, pointed out a group from which he had picked a thousand flowers the day before and they could hardly be missed. Violets are not the only things done well here, as the hybrid Perpetual Roses and a few well-grown Orchids testify. The most successful Carnations here are Lizzie McGowan, Mrs. Fisher, Tidal Wave and Ferdinand Mangold. Below the benches, in the cool house, some beds were carrying a good crop of Mushrooms, as well as Rhubarb and Sea Kale.

A short walk from Mr. Nevins' estate brings us to Mr.

William Nicholson's establishment, in Framingham Centre. This is one of the best-known florists' places in the neighborhood of Boston. Carnations make the leading feature of the place, and all the standard kinds are grown in quantity. The new varieties, Nicholson and Ada Byron, while not successful with some growers, here make a splendid show, the plants being smothered with flowers and buds, borne on long stems. Other kinds specially well grown are Mrs. Fisher, Hector, F. Mangold, William Scott, Daybreak and E. G. Hill. The sale of rooted cuttings is here a specialty, and many thousands are now in the cutting-benches. Roses fill a house one hundred feet by twenty, and a similar-sized house is devoted to Tomatoes, the kind chiefly grown being Nicholson's Hybrid, the standard forcing variety for the Boston market, and raised some years ago by Mr. Nicholson.

Taunton, Mass.

W. N. Craig.

Meetings of Societies.

The American Carnation Society.—II.

THE display of cut flowers excelled in abundance, variety and general quality all previous exhibitions of the Carnation Society. Our report of the meeting concludes with some notes on the more promising seedlings, as well as the standard varieties in the leading classes and colors :

Something like seven thousand flowers, including seedlings, were staged at the exhibition, and two-fifths of these were different shades of pink. White flowers were next to the pink ones in number, and then scarlet, yellow, variegated and crimson followed in the order of abundance. Among the flowers of different shades of pink, William Scott had no peer, and in the classes for light pink flowers it captured nearly every prize. Larger flowers were shown of some varieties, such as Nicholson, but the stems were so weak that they hung over the edges of the vase, or else they had some other defect to counteract their superiority in size. Altogether, William Scott can be pronounced the best all-round pink Carnation in cultivation to-day; its superb color, good stem and healthy growth making it a success wherever tried. Next to William Scott, Daybreak was shown more largely than any other pink variety, and it was of very good quality. These two sorts are unquestionably the best of their color up to date. The old Tidal Wave, now seldom seen, was remarkably well shown by Dailedouze Brothers. The flowers were large, carried on stiff stems, and they looked fresh at the close of the exhibition, and their rich dark rose-color was unequaled, or, at least, unexcelled by any of the newer kinds. The best white was Storm King, as shown by Mr. C. W. Ward, of East Moriches, New York. It is a strong grower, with stout stems and large well-formed flowers. Alaska, with which Mr. H. E. Chitty, of Paterson, New Jersey, won the prize for the best vase of a hundred white flowers, is a cross between Puritan and Lizzie McGowan. It has a decidedly stouter stem than the latter parent and a flower of much the same form. The second prize in this same class was won by a seedling of Mr. Chitty's, which he calls No. 150. These were undoubtedly the finest flowers in the class, but they lacked strength, both of stem and calyx.

In the scarlet class, the new Jubilee, as exhibited by Mr. Hill, of Richmond, Indiana, was easily first. The color of the flower is a light scarlet, rather dull, and the petals are not fringed at all. It is very sweet-scented, too, which is rather unusual in a scarlet flower. The stems were remarkably strong, so that every individual flower stood erect, but the plant showed unmistakable signs of rust. Hector, which secured the second prize in this class, is a finely fringed large flower of a much brighter color than Jubilee, and if it had the stem of the latter it would be decidedly the better of the two. The Stuart was not largely shown. According to Mr. Dorner, who raised it, it is only seen at its best in a solid bed and kept under glass all the time. The new Meteor was quite the best of the few crimson sorts which were shown. In form of flower, stiffness of stem and strength of calyx this seems to be an acquisition. Jacqueminot was represented by one vase with remarkably strong stems, and although the flowers were smaller than those of Ferdinand Mangold, they were of a pure rich color, and the plant must be considered an acquisition to the crimson class.

Buttercup, which is very fickle in its behavior and has had to give place to Bouton d'Or, a beautiful lemon-yellow, and to the newer Dean Hole, was shown in admirable condition by Mr. Southworth, and if this old variety could always be grown in such form there is certainly no yellow equal to it. Helen Kel-

ler was shown by several growers in fine condition, and was far the best of the fancy marked flowers staged. Edwin Lonsdale's lot was superb in every respect, and the plants seem to succeed admirably throughout the Philadelphia district. Such flowers as these were never seen before in Boston. Minnie Cook, Mr. Chitty's new variegated variety, followed Helen Keller as the next best in its class, and it won the first premium for a vase of a hundred flowers.

Eighty new seedlings were shown, twenty-nine of which were pink, fifteen white, ten yellow, nine variegated, five crimson or scarlet, and the remainder some odd shades of color. These flowers were in many cases admirable, and showed a marked advance over the kinds now grown. Triumph, from Messrs. Hill & Co., was a specially noticeable pink flower with the best stems of any plant of its color, large, elegantly formed and a most pleasing shade. Among the dark pinks was Mr. May's Lena Saling, of which we have already spoken. It is somewhat lighter than Tidal Wave in color, with large flowers of a similar form and a perfect stem. Maud Dean, of a soft fawn color, paler than Daybreak, and shading to rose in the centre, Mr. Shelmire's Silver Queen and Mr. Hill's deep pink Arcadia were all good. Della Fox, described in last week's report, and commended because shown, not only as a cut flower, but also as a growing plant, was notable for the delicacy of its pink color. Besides Storm King and Alaska, of which we have spoken, Mr. Tailby showed a seedling called the Poor Man's Friend, with an immense flower, but rather tender calyx. Mr. Fisher showed Crystal, another large flower, but feeble in the stem. Of the new scarlets and crimsons there is no need to speak of any besides Meteor and Jubilee. Mr. May's Dean Hole is a fine bold yellow of first-rate habit, and Tailby's Henrietta Sargent had a clearer color than any other variety shown. Perhaps the best of the new variegated ones was Aramazinda, of Messrs. E. G. Hill & Co., who were the largest exhibitors of seedlings, and who staged twenty varieties, not one of which was ordinary. All the flowers were fine, the vigor and strength of their stems were noticeable, and at the close of the second day's exhibition nearly all of them seemed perfectly fresh, although they had been carried fifteen hundred miles, while most of the flowers from exhibitors in the neighborhood of Boston were closed up before the show was open or drooping hopelessly over the edges of the vases. Mr. Dorner's new variety, Bridesmaid, which many were anxious to see, arrived in a sleeping condition, and Simmons' Rose Queen was not exhibited. Altogether the seedlings were superior, and showed the usual annual advance in the quality of Carnations.

Recent Publications.

The Forest Flora of Japan. By Charles Sprague Sargent, Director of the Arnold Arboretum. Houghton, Mifflin & Co., Boston and New York.

The notes for this volume were collected by Professor Sargent in the autumn of 1892 when traveling in Hondo and Yezo, and they were first printed in the issues of this journal during the year 1893. Our readers, therefore, need no information as to the particular way in which the subject has been treated, nor need they be reminded that the book has a peculiar and practical value for American planters, since the climatic conditions of north-eastern Asia are so similar to those which prevail here, especially in our Atlantic states, that the trees and shrubs of one region can usually be trusted to make themselves at home when removed to the other. The original pictures are here reproduced, and with the beautiful type and printing on broad-margined pages the volume is a most attractive one.

Notes.

Dr. Hoskins calls attention to the fact that the greater portion, if not all, of the Russian Apples seem able to resist the scab fungus.

The peach-growers of the southern states declare that the freezing weather has not destroyed the fruit-buds, as was reported, but that it has held the buds back so that the bloom will be later than usual, and, therefore, ensure the blossoms and the newly set fruit from injury by late frosts.

Mr. Thomas Meehan takes note of the fact that the beautiful Cypripedium insigne is a good window plant. Its native habitat is in deep shade, so that the obscurity of a dwelling-

house is rather agreeable to it, and as it naturally flowers in winter it needs no forcing to make it bloom. A plant is mentioned which is growing in an eight-inch pot under ordinary living-room conditions, and during the past winter it had seven flowers, which began to open early in December and have continued one after the other until February.

The most conspicuous objects in the windows of the florists' shops just now are compact plants of Azalea in full bloom. It is rather strange that the newer varieties are mostly those which bear double flowers, since the single-flowered kinds are generally more effective. The fashion, imported from France, of swathing the plants as well as the pots with ribbons and paper and decorating them with bow-knots of various material has nothing to commend it. Much of the beauty of a well-grown plant is in its form, and when this is hidden by upholstery the plant loses half its charm.

A broad sheet, entitled *The Spray Calendar*, prepared by Mr. E. G. Lodeman, has just been issued by the horticultural division of the Cornell Experiment Station. It gives a list of the remedies for the more dangerous fungous diseases and insects, which are to be used on different fruits and crops. It tells how, when and how often to apply these remedies, and in different kinds of types it indicates the comparative importance of the applications to be used. All the needed facts are grouped together in a convenient form, so that this will not only be efficacious in instructing those who are not well informed on these matters, but will serve to remind those who already know how to make these applications when the time for using each has arrived.

An English lady, Miss Wilkinson, has, in recent years, made herself widely known as a landscape-gardener, capable of undertaking public works and of carrying them to completion under her personal supervision, and Vauxhall Park, in London, opened to the public last year, is one of her latest works. Commenting upon these facts, and characterizing Vauxhall Park as "a remarkable work in every respect," the *Revue Horticole* recently said: "So we see that a woman has entered the professional camp, the camp of practicing artists, and has proved her right to a distinguished place in it by worthy results. It seems a curious sign of the times. Who knows whether the delicate gifts of woman may not introduce valuable innovations, unknown refinements, into our gardening conceptions?"

The current number of *Scribner's Magazine* contains an article on bedding-plants, by Samuel Parsons, and it is illustrated by some excellent pictures taken from actual groups in the different parks of the city. All of these beds are easy and natural—that is, they show no trace of formality or mannerism—and there are accompanying maps which explain the method of arrangement, the plans having shaded sections to indicate the particular plants which are used in every location. The pictures show how much better this irregular planting is than straight ribbon lines or geometric beds, and the maps explain that the irregularity is no haphazard mingling together of different forms, sizes and colors, but a well-studied system, analogous to that which a good planter would use in disposing trees on a wood border, or of shrubs when massed for general effect. Tender bedding-plants are always expensive; they are often misplaced, and where they can be made effective masses of select woody plants and perennial herbaceous plants are preferable, as a rule, and the shrubs will have a beauty of their own all winter. But in large places and public parks bedding-plants will add variety to the garden effects aimed at, and the grouping described and figured in this article is much more satisfactory than the regular and rigid carpet patterns so often used. Particularly pleasing are the examples where single plants or groups of two and three have broken away from the mass and strayed over upon the turf.

Both in England and in America "lumber" means useless, bulky things which are cumbersome or in the way. In America only it is also used as a synonym for "timber sawed or split for use." This fact all modern dictionaries note, but even the American ones make no attempt to trace its origin. It is interesting, therefore, to find such an attempt in an article recently published in the *American Architect and Building News*, and signed by Mr. C. W. Ernst. In what Mr. Ernst calls "the Tudor period" of Boston's existence, between 1630 and 1720, its chief article of trade, he says, "was wood in all its forms, especially for fuel and building purposes. The article had to be brought to Boston by boats. These boats were apt to discharge at random. The harbor front and wharves were accordingly 'lumbered up' with all sorts of forest products to the inconvenience of the public, which traveled pre-

ferentially by boat and frequented the wharves relatively more than we do." Therefore, in 1663, the police "were instructed to 'clear the ends of all streets and wharves that but upon the water from all lumber and other goods.' This is the first use of the word lumber for sawed wood. The Boston Town Order of April 27, 1663, called the sawed wood the timber (hewn), the masts and other wood brought to town by boats 'lumber,' because the cargoes lumbered up the harbor-front. The new meaning was immediately adopted, and lumber, in the sense of sawed wood, is the least restricted as well as the earliest of all Americanisms."

During the year 1894 the importations of bananas into the United States amounted to nearly 18,000,000 bunches. Heavy cyclones throughout the West Indies last autumn destroyed much of this year's crop, and the few cargoes now coming from Jamaica and Cuba bring high prices, some bananas of the first grade selling last week for \$1.40 a bunch by the truck-load. Nearly one-third of all these imports usually come from Jamaica alone, so that the market has been considerably affected by the shortage. But change in the wholesale prices of bananas does not seem to affect the prices asked for them by retail dealers, who the year through offer three of the best quality for five cents, and fairly good bananas for a cent each. W. & C. Smith, on Liberty Street, now have a supply of the small Lady-finger banana, from Colon, for which buyers acquainted with their delicate flavor pay twenty-five cents a dozen. Unusually fine plantains, each twelve to fourteen inches long, sell at the same place for fifty to sixty cents a dozen. Partially ripened ones are used by Spanish residents for boiling, while the fully ripened fruit, with blackened skin and softened pulp, are considered preferable for frying. Spitzenberg, Northern Spy, Greening, Ben Davis and Baldwin apples are regularly quoted in the wholesale market reports, and form the staple supply. These sorts cost from \$4.00 to \$7.00 a barrel for good grades, some exceptionally choice and fancy apples commanding even higher prices. A selected lot of Baldwins of uniform size, deep, rich color and high quality recently brought \$10.00 a barrel at wholesale. Retail dealers in high grades of fruit offer beautifully colored Winesaps and Northern Spies. Newtown Pippins, from California, cost fifty cents a dozen, and the more acid Pippins from Ulster County, in this state, bring seventy-five cents. California Seckel pears, held over in cold storage, may still be seen in the fancy fruit stores and cost from sixty cents to \$1.00 a dozen. The last specimens of the larger D'Alencon are seventy-five cents to \$1.25 a dozen, while well-ripened Easter Beurres and P. Barrys bring seventy-five cents to \$1.50 a dozen, and Winter Nelis fifty to seventy-five cents. California strawberries, looking unimproved by their long journey, cost seventy-five cents a pint, and the first strawberries from Lakeland, in southern Florida, fresh and bright and in good order, are sold at the same price. In addition to damage to the orange crops in other parts of the world, there is now well-authenticated information that the crop in Sicily has been damaged by hail storms. Some 40,000 boxes of this Mediterranean fruit will be sold in this city this week, but even so large a quantity does not supply the loss of the Florida crop, since at this time last year 60,000 boxes of Florida oranges made an ordinary week's supply here. Some extra-sized Navel oranges, from Florida, held here since before the freeze in that state, sell for \$2.00 a dozen. They are too large to be profitable, even at this price, since they measure twelve inches in circumference, and the largest actually weigh two pounds each.

Mr. John J. Thomas, one of the most eminent pomologists of the country, died at his home in Union Springs, New York, on the 22d of February, at the ripe age of eighty-five years. From his father, who was a naturalist and explorer of distinction, he inherited the power of original research which led him to investigations and experiments which have been useful in so many branches of horticulture. Among his works, *The American Fruit Culturist*, which was first published fifty years ago, still remains probably the most useful work of its kind. It has been revised many times to keep pace with the advance of pomology in this country, and the latest labors of Mr. Thomas were given to the preparation of a new edition which is to be published in May. Nine volumes of miscellany, entitled *Rural Affairs*, which are selections from the *Country Gentleman*, of which he was an associate editor, and another interesting work on *Farm Implements and Machinery*, were prepared by him and they rank among the most useful manuals for a country library. Personally, Mr. Thomas was a man of great simplicity and sincerity of character, combining sturdy integrity with a rare refinement, gentleness and unflinching charity.

The Forests of the Wabash Valley.

THE composition of the remarkable forests which, in spite of the terrible inroads that have been made in them during the last twenty-five years, still cover considerable portions of the region in southern Illinois and Indiana watered by the Wabash River and its tributaries, was first made known to the scientific world by a paper published in 1882 in the fifth volume of the *Proceedings of the United States National Museum*, by Dr. Robert Ridgway, the ornithologist of the Smithsonian Institution.

Dr. Ridgway was born in Mount Carmel, on the banks of the Wabash River, nearly opposite the mouth of White River, and his early work in his chosen field of science brought him into familiar intercourse with the trees of that region, which he has studied faithfully and lovingly whenever opportunity offered until the present time. By a piece of very great good fortune his investigations have, moreover, been supplemented by those of another naturalist, Dr. Jacob Schneck, who for many years has lived in Mount Carmel and has also been specially interested in trees. The result of this fortunate association has been that the forests in the neighborhood of the mouth of White River have been more carefully studied than those in any other spot of equal interest west of the Allegheny Mountains. Other regions with a similar climate and with as good soil can be found in western Kentucky and Tennessee, in south-eastern Missouri, eastern Arkansas, and in the delta of the Yazoo in western Mississippi, and may, perhaps, produce as remarkable individual trees in as great a variety of species, but none of them have been as carefully studied, and, until some other forest containing a greater variety of trees and larger individuals can be found, that of the lower Wabash valley must be considered the most remarkable aggregation of trees in the north temperate zone. On the western slopes of the Big Smoky Mountains, in Tennessee, there are wonderful trees in great variety, and individuals of some species, although not so tall, probably, produce in that forest their largest trunks; and in climbing about four thousand feet from the banks of the little Tennessee, in North Carolina, to the summits of these mountains one can count nearly fifty arborescent species, although individual trees are smaller than on the western flank of these mountains.

In a second paper on the Wabash Silva, recently published in the seventeenth volume of the *Proceedings of the National Museum*, Professor Ridgway shows that the number of indigenous arborescent species in the Wabash valley south of the mouth of White River is one hundred and seven, or more than a quarter of all the arborescent species in North America north of Mexico, and even this number can be slightly increased, as one or two species of *Crataegus*, overlooked by Professor Ridgway, grow near Mount Carmel.

Some idea of the surprising richness of the forest-flora in this region can be obtained by an examination of Dr. Ridgway's list of trees growing on restricted areas. On a tract of seventy-five acres he found fifty-four species of trees, and another of twenty-two acres contained forty-three species. On a tract of forty acres one mile southeast of Olney, in Richland County, Illinois, what the author modestly calls an imperfect survey of the woods shows thirty-six species. The nearest approach to such a concentration of tree species in a restricted area is in central Yezo, where Professor Sargent found sixty-two species and varieties of trees growing in the immediate neighborhood of Sapporo at practically one level above the sea.

The height attained by these Wabash valley trees is as remarkable as the number of species in the forest. Individuals of forty-two species reach a height of one hundred feet, and those of twenty-one species grow to the height of one hundred and thirty feet. Individuals one hundred and fifty feet high of thirteen of these species have been measured. A specimen of *Quercus Texana*, called *Quercus coccinea* by Dr. Ridgway, the tallest of the Wabash Oaks, and, perhaps, the tallest Oak in North America, measured one hundred and eighty feet, and a Tulip-tree one hundred and ninety feet; a Pecan, the tallest Hickory, one hundred and seventy-five feet; a Cottonwood (*Populus monilifera*), one hundred and seventy feet; a Bur Oak (*Quercus macrocarpa*) one hundred and sixty-five feet; while, in addition to the trees already mentioned, a Liquidambar and a Black Oak attained a height of one hundred and sixty feet. The size of the trunks of some of these trees, measured at three feet above the surface of the ground, is hardly less remarkable than their height. A Sycamore (*Platanus occidentalis*) girted thirty-three and a third feet; a Tulip-tree twenty-five feet; a White Oak twenty-two feet; a Black Walnut twenty-two feet; a Black Oak twenty feet, and a Texas Oak twenty feet. In comparison with such trees, the inhabitants of eastern forests, where trees one hundred feet tall are extremely rare, appear like pygmies, and persons familiar only with forests of the Atlantic seaboard can form no idea of the magnificence of these trees, the last remaining vestiges of the forests which covered the valley of the Mississippi when the white man first floated down its placid waters.

This region is the home of some of our most beautiful and valuable trees. On the bottom-lands of the rivers the Pecan and the great western Hickory (*Hicoria laciniosa*) grow with all the Swamp White Oaks, the Pin Oak, the Texas Oak, and that remarkable form of the Spanish Oak, which, usually an upland tree, sends up on these bottom-lands a tall, beautiful shaft covered with pale bark, which might readily be mistaken for the trunk of one of the White Oaks. The illustration on page 104, made from a photograph, for which we are indebted to Dr. Schneck, represents one of these trunks. The attention of scientific men is first called to this variety in Professor Ridgway's second paper, although it has long been known to southern lumbermen. Common in the Yazoo delta and in eastern Arkansas, and not rare in northern Alabama and western Florida, it is valued as a timber-tree, and is said to produce wood equal to that of the White Oak. In the Wabash valley the southern Cypress (*Taxodium*), the Water Hickory, the Water Locust and the Planer-tree, all denizens of the south, find their northern homes, and there the rare Swamp Cottonwood grows to its largest size, and the Catalpa displays its greatest beauty. In these lowland forests great

lianes festoon the trees, and Dr. Ridgway tells us of Grape-vines with stems more than a hundred feet long and more than a foot in diameter, and of Aristolochias, Poison Ivies and Bignoniæ nearly as large. No other American forest-scene is more beautiful, and certainly no other forest of deciduous trees, for it must be remembered that in all this great collection of trees there is not a single species with evergreen leaves, is more interesting. A view in one of these bottom-land forests, with masses of the Virginia Creeper clothing the trunks of the trees, appears in the illustration on page 105 of this issue, made from a photograph, for which we are also indebted to Dr. Schneck. No picture, however, can give an idea of the stateliness and grandeur of these noble trees, or of the luxury of the annual and perennial plants that cover the forest-floor with almost impenetrable thickets.

In ending this brief notice of Dr. Ridgway's most interesting and important contribution to dendrological science, we cannot refrain from the hope that equally well-trained and enthusiastic observers may appear to study the composition of other forest-regions in the Mississippi basin before the demands of a larger population destroy the noblest deciduous-leaved trees that the eyes of man have rested on.

THE most encouraging sign that the time is approaching when our wasteful methods of lumbering will give place to something like an intelligent system of forestry, is the attitude of the lumbermen and the lumber-trade journals. Only a few years ago anything like a criticism of the prevalent methods of clearing away the woods was resented and sneered at as sentimental, and any prediction that the timber supply could be exhausted within a given number of years was attributed to ignorance. In these days, however, we expect to see in the lumber-trade journals sound advice about forest-preservation, and the lumbermen, whose business it has been to cut and market timber, are now thoroughly alive to the fact that they must look forward and provide for the future as well as for the present. All this was clearly shown at a late meeting in Boston of the vigorous Northeastern Lumbermen's Association. After the inevitable banquet of such occasions the keynote of the most effective speeches was "the slaughter of the forests must be diminished." Mr. George B. James, who presided, affirmed that the output of New England forests depends upon their intelligent management; that under proper forestry conditions the supply of lumber may be continued for many years to come; without proper management their market value is soon destroyed and generations must elapse before timber can be reproduced upon land that is stripped of every vestige of growth. When lumbermen clearly apprehend that the future of their business depends on the care with which our forest-resources are husbanded, we can begin to hope that the end of useless forest-destruction is at hand.

Notes on the Distribution of the Yellow Pine in Nebraska.

THE central portion of Nebraska is occupied by a peculiar region covering fifteen to twenty thousand square miles, known as the Sand Hills, now practically treeless, except in the deep cañons, and made up of an undulating surface of grass-covered sand, not infrequently consisting of deep valleys bordered by very steep hills from two to four hundred feet high.

A somewhat prolonged study of these Sand Hills has led me to the inquiry whether they have always been treeless. They bear no little resemblance to many regions still covered with Pines in other portions of the United States. I have traveled for days through Pine-forests in Michigan, which if denuded of trees would be much like our Sand Hills, both as to soil and surface configuration. It is not impossible that forests formerly covered the Nebraska

Sand Hills, as in places they still do the sand hills of Michigan.

As we pass up the cañons of the larger streams we find trees. These are mainly of eastern species, and it is possible that they migrated hither, and never spread from the narrow cañons. This appears to have been the opinion of Hayden and many other of the early explorers of the Plains, and I think it is still the prevailing belief that these hills were always destitute of forests. Let us, however, consider the following facts:

(1) There are many isolated cañons which contain trees.

This suggests that either (a) the seeds of these trees must have been distributed by birds or winds, or (b) a former more general distribution. It is not probable that birds and winds carried the seeds to these cañons. The physical barriers are often too great to warrant us in assuming that birds were the agents in distributing the seeds from which sprang the forests in isolated cañons. Nor can we assume that winds carried the seeds. We are forced to assume that the forest-areas must have formerly been more extended, sufficiently so to connect these isolated cañon forests with one another.

(2) There are in these cañons western as well as eastern trees and shrubs.

This fact is significant, as it requires some further explanation of the origin of the present cañon flora. These western trees and shrubs could not have reached their present stations unless conditions favorable to forest-vegetation were formerly much more general than now.

(3) The Yellow Pine, *Pinus ponderosa*, var. *scopulorum*, of the Rocky Mountains, now grows with other trees upon the hills of Pine Ridge from the Wyoming line, in Sioux County, to the Dakota line, in Sheridan County.

In this region there are eastern and western trees, and they are growing upon the hilltops as well as in the valleys and cañons. I have seen hundreds of trees of Yellow Pine growing here upon the open hillsides and upon the most exposed buttes.

(4) The Yellow Pine is now to be found in the cañons of the Niobrara River and its tributaries as far east as the border of Holt County.

In the cañons the Pines are growing thrifly, and in many places young trees are springing up abundantly. Several years ago I saw such a new growth of Pines in the northern part of Brown County, where the cañons are still full of fine healthy Pine-trees. There is nothing in these cañon Pines to suggest that conditions are now less favorable than they formerly were, but when one studies the borders of the cañons carefully, evidence is not wanting to the contrary. Here trees are found upon the most exposed points and crags, where it would now be practically impossible for them to obtain a foothold. Many of them are evidently the veterans holding desperately the stations otherwise practically abandoned by the species in its losing fight against unfavorable conditions.

(5) The Yellow Pine extended eastward along the North Platte River and the Lodge Pole Creek to Deuel County, until the pioneers destroyed them forty or fifty years ago.

In some places this destruction has been so complete that scarcely a trace now exists of the Pines. Nothing could better illustrate the rapidity with which all traces of these trees may disappear than their history along these two western streams.

(6) The Yellow Pine grew in considerable quantities in at least one station on the Republican River until destroyed by the early settlers.

Until within a few months it was generally supposed that the Yellow Pine never had grown naturally in the Republican valley. Last fall Mr. E. M. Hussong, of Franklin, in Franklin County, found several decaying stumps of Pine on the south side of the river, near the town, and upon close inquiry learned from the oldest settlers that in the early days small Pine-trees had been dug up in the cañons and on the bluffs and transplanted to dooryards and gardens, while the large trees were taken for fuel and fencing

purposes. That the Yellow Pine was a native tree at this point is proved beyond question, and we are led to suspect that an equally careful search will show its former existence in other places in the valley.

(7) In the Loup Valley there are Yellow Pines on the South Loup, Middle Loup and North Loup Rivers.

These occur in widely isolated cañons, which have no forest connection with one another. Since all the branches of the Loup head in the Sand Hills, the occurrence of Pine on their borders is very suggestive.

(8) Logs and fragments of Yellow Pine-trees occur here and there in the Sand Hills.

A few years ago an old hunter at Norfolk told me that he had frequently found old pine logs in tramping over the Sand Hills, and that these had often served to make his camp-fire. Professor Bruner a few years ago saw a settler's wagon in the south-western part of Holt County on which were fragments of pine wood cut from a pine log found on the top of one of the hills. Professor Samuel Aughey also, who traveled over the state a great deal in the early days before the hunters had used up all these fragments for fuel, states that he has repeatedly found such logs or fragments.

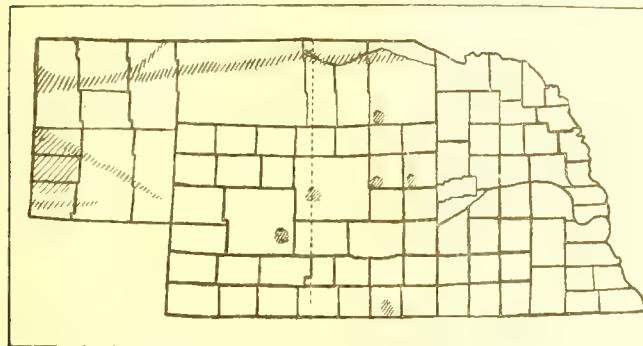

Fig. 15.—Present and past distribution of Yellow Pine in Nebraska.—See p. 102.

Now, add to the foregoing facts another which but recently came to light, and which shows that in places from which all external traces of the Pine have disappeared they may have existed in comparatively recent times. A few weeks ago Mr. I. A. Fort, of North Platte, placed in my hands a fragment of a pine stump dug out of the ground in Conroy Cañon, in Lincoln County (on section 17, township 11, range 27), about fifteen miles south and eighteen miles east of the city of North Platte. This is about one hundred miles east of its range on the Platte River as hitherto known, and in a locality in which the former presence of Pine was unexpected. Putting all these facts together (see map), I feel warranted in concluding that the area of Yellow Pine in this state must have been formerly much greater than it is to-day. I think I can safely say also that it is reasonably probable that the Sand Hills were once wooded with the Yellow Pine.

Lincoln, Neb.

Charles E. Bessey.

Troublesome Grasses in Southern New Jersey.

THE Grasses are, by far, the most important order in the vegetable kingdom, yet we find even in this well-regulated family many species that are worthless, and others that are worse than worthless—actually vicious. Like most noxious weeds, our troublesome grasses are mainly foreigners. The Crab-grass, *Eleusine Indica*, as its name indicates, comes from the east, and is a nuisance in newly formed lawns and in dooryards generally. It has ascending wiry stems and is not at all handsome. Another species, *E. Ägyptiaca*, has a more creeping habit; it runs along, rooting at the joints as it goes. It often gets into Currant rows and among other small fruits. I have seen a single plant some yards in length. Sometimes it climbs up into the bushes among which it grows. In uprooting it, if a single joint is left a new plant is speedily formed.

Fortunately, both this and *E. Indica* are annuals and more easily subdued than if they had perennial roots.

The Couch-grass, *Agropyrum repens*, is naturalized from Europe, and is one of our worst perennials. It increases rapidly by long running root-stocks. We have several forms of this species which seem to be indigenous. It is one of the most troublesome weeds in southern New Jersey, especially near the coast. Our Wheat, *Agropyrum vulgare*, belongs to this genus, the good and bad being often closely related in the vegetable as well as in the animal kingdom. Cheat, or Chess *Bromus secalinus*, is very troublesome here, especially in half-neglected orchards and vineyards. Last year I noticed whole acres completely covered. This, too, comes from Europe, and it is pretty well known everywhere. Two or three species of Foxtail Grass are troublesome in cultivated grounds, all of which are from Europe.

The Bermuda, or Scutch Grass, *Cynodon dactylon*, is not pretty on our lawns, as it is a coarse, creeping, much-branched grass, and difficult to eradicate where it gets a firm foothold. It is a perennial and also comes from Europe, and is sometimes cultivated for pasture. I am sorry to say that one of the most pernicious of all our grasses, the Bur-grass, *Cenchrus tribuloides*, is a native of southern New Jersey. In neglected places, and in vineyards and orchards which are plowed only once or twice a year, this pest is almost unbearable. Several years ago I became possessor of a place some five acres in extent, mostly in fruit—vines and trees—which had been neglected for years. The entire place was almost literally covered with Bur-grass, and it has been a continual war of extermination ever since. Some three acres of Grape-vines were uprooted and put into civilized grass, which has effectually routed it from that quarter, and an acre or more was put into lawn-grass, which has about eradicated it here. But the sharp-barbed burs which cover the seeds are everywhere, and the plants steal in among Currant and Gooseberry rows and wherever they can find a bare spot that is not often stirred. This terrible pest extends all along the coast and about the great lakes and rivers to the southwest as far as southern California.

Two other species of this Bur-grass occur in southern and lower California. *Cenchrus Palmeri* has more wicked-looking spines than ours; when young it is greedily eaten by cattle, but they give it a wide berth as soon as the involucres harden, and the injury caused by its burs more than outweighs its value as a forage-plant. *C. myosuroides* is another species growing in the south-west. This is less objectionable than the others, and produces a good crop of forage when young, and the prickly seed-envelopes are not quite so bad as the others.

The Nut-grass, *Cyperus rotundus*, is a great plague here in cultivated grounds. It is not a true grass, however, but belongs in the vast family of Sedges. The members of this great order are usually harmless, and mostly useless, except to beautify the earth, often growing, as they do, luxuriantly where other things refuse to thrive. This Nut-grass is said to come from the more southern states, but I am sure that it must be indigenous here. At all events, ever since the settlement of Vineland, it has been a pest in cultivated grounds. It is distributed both by seed and by small potato-like tubers, which are produced on long, slender root-stocks running out from the plant in every direction, which in sandy soil reach a yard or more in length, and the plow and cultivator help to distribute the pest by breaking the runners and scattering the tubers, when each will make a new plant if not constantly kept in check.

I subjoin an extract from an article sent out by the Government on the best means of eradicating Coco, as this pest is sometimes called :

The plan of campaign to extirpate Nut-grass is simply to prevent it maturing seed above ground. Nearly everybody thinks that the nuisance reproduces itself from the nutalone, whereas it propagates a thousand times more from the seed. Hence, to effectually and quickly destroy Nut-grass on any land infested with it, the soil should be frequently stirred during the grow-

ing period of summer so as to stimulate each nut tuber and seed to sprout. It is a waste of effort to attack Coco in winter, either by digging or plowing, or turning hogs on it. The best time for fighting it is between midsummer and frost time. Although myriads of the sprigs will show themselves above ground in a day or two after each working of the soil, even in the spring months, yet no seed-stem will shoot up till late in the season, and the secret of success, as before remarked, is

Fig. 16.—Spanish Oak, *Quercus ilex*.—See page 101.

merely to cut down every tall stem, while in the flowering stage at the latest, and the sooner the better. The old method for destroying Coco, by cutting it off under the surface of the ground every time a sprig appears above the surface, is a useless expenditure of labor. The ground should be often stirred with the plow or hoe, from April to frost, as before mentioned, to make every nut and seed come up if possible, and as soon as possible, but there is no urgent necessity, as far as eradicating the grass is concerned, to kill its sprigs until they begin to shoot up seed-stalks. For this purpose it is only requisite to plow or chop down the grass at the regular intervals of working Indian Corn, Collards, or any other crop. Still it is advisable to plant the land in some tall-growing crop which shall neither cover nor obscure the Coco seed-stems, and thus keep them from being observed and destroyed. By the above method two years are ample time in which to rid any ground of Coco. In fact, one season is sufficient to eradicate it, except that a few scattering sprigs will show themselves in subsequent years, which can easily be prevented from going to seed by close attention. One cause that has enabled Coco so long and so defiantly to hold its sway in the south is that we have so few crops which are hoed or plowed in the fall of the year. This, together with the popular error that Coco propagates from the nut alone, explains the whole story of its universal triumph over the patience, sweat, curses and blows of the millions who have warred on it.

Vineland, N. J.

Mary Treat.

Plant Notes.

KERRIA JAPONICA.—A recent number of *The Garden* speaks of the cheerful green tint of the long slender branches of Kerria Japonica in the winter-time. We can add that what is true of this plant in the soft climate of

England is equally true here, where the yellowish green stems of the Kerria, better known here as the old-fashioned Corchorus of our gardens, rival the Willows and Cornels in their pleasing effects, especially when they stand out in contrast to the drab or dead brown of many other shrubs. The double-flowered form of this Kerria, which is closely allied to the Pearl Bush, or Exochorda, has long been a favorite in country gardens because of its easy propagation, its ability to endure considerable shade and to the fact that it bears a few scattered flowers occasionally all summer long. A much more beautiful shrub is the rarer single-flowered form, the flowers of which are nearly an inch and a half across, and produced singly on slender stalks, where their five bright yellow petals and numerous long stamens are seen to first-rate advantage against the light green foliage. This was one of the first plants ever introduced from Japan, and it is still among the very best. As we have said, it is beautiful in winter, beautiful in early June with its bright flowers, and in early November it is one of the most distinct ornaments of the shrubbery, when its foliage turns to a clear sunny yellow, which is unsurpassed. In good ground the Kerria attains a height of six feet or more, and it becomes as broad as it is high. It is perfectly hardy in this latitude, although farther north the ends of the branches are sometimes killed in winter. The single-flowered kind is quite superior to the other, but, for some reason, it is seldom seen in shrubberies, and, indeed, until recently it could hardly be found in American nurseries.

SYMPLOCOS CRATEGOIDES.—A correspondent inquires the name of the Japanese shrub with blue berries. There are species of Viburnum, Vitis and other genera with fruits more or less blue or purple, but perhaps the plant sought for is *Symplocos cratægoïdes*, or, as it was formerly called, *Symplocos paniculatus*, a hardy shrub sent to this country from Japan nearly a quarter of a century ago and distributed by Messrs. Parsons, of Flushing. Though it has been known so long it is still by no means a common inhabitant of our gardens, although its clean foliage, graceful flowers and almost unique fruitage ought to command a place for it in every considerable collection. It was figured in GARDEN AND FOREST, vol. v., page 89, where the white flowers, each less than half an inch across when expanded, and borne in short loose panicles, and the racemes of fruit each one being the size of a pea, and borne on the last year's growth, are well shown in Mr. Faxon's drawing. But what gives the plant its singular value is the deep ultramarine blue color of its fruit, which is borne in great abundance. It is a broad tree-like shrub with dark green leaves, softly pubescent on the under side, and which have so far in this country been free from the attacks of insects and fungi.

DIPLARRHENA MORÆA.—This is an interesting Tasmanian Iridaceous plant with curious habit, which bears very pretty flowers. The plant has narrow leaves, which grow in clusters, and increases by new shoots from its short creeping rhizomes. It also throws out thin wiry stems from the bases of the clusters, and on these flowers are borne singly, but in frequent succession. These stems, which are not larger than an oat-straw, keep growing in length, and finally produce new plants. Mr. Endicott, in an early number of GARDEN AND FOREST, spoke of a stem that had grown to a length of ten feet in his greenhouse. The flowers are charming in appearance, but very fugacious, lasting at most only a few hours. They are Moræa-like in form—nearly flat. The large segments are white, with orange spots; the small segments are white and narrow. The stigmas form a purplish central crown. The flower is about two inches in diameter, and is followed by seeds borne in long-pointed three-sided capsules, the planes of which are concave. As will be seen, this plant is readily increased. It offers no difficulties in cultivation, and there are few greenhouse plants which will survive more neglect, as it seems insensible to drought.

JATROPHA PODAGRICA.—This is an interesting euphorbiaceous plant from New Guiana. Cassava and tapioca are made from the roots of some species of Jatropha, but this

one is noteworthy for its curious stem and the peculiar arrangement of its flowers. The plant grows readily from seed, and has a gouty stem, about a foot and a half high. The goutiness appears at the top, the stem being crudely described as like an inverted ten-pin. The smooth leaves are five-lobed, four or five inches across, and usually disappear late in the year. The flowers are borne from the top of the stem on short peduncles, and are small bright coral red, and in racemes irregularly arranged, so that the effect is of a bunch of coral. Well-established plants flower frequently, whether the plant is leafless or otherwise.

Cultural Department.

Germination of Black Walnuts and Acorns.

M R. JACK'S articles in *GARDEN AND FOREST* (vii., 135; viii., 6) on "Patience with Germinating Seeds," and "Germinating Nuts and Acorns," recall an interesting observation lately made on the retention of vitality in black walnuts. So far as I know, the behavior of this seed appears to be quite phenomenal.

under the direction of the Division of Forestry, the nuts having been kept during the preceding winter spread out in a thin layer on the ground, with a light cover of débris. The soil was a slightly loamy sand, and when planted the nuts were covered to a depth of from two to four inches. Within ninety days after the planting, a large percentage of the nuts germinated and the plants made a vigorous season's growth. One year from the planting (March, 1894), in taking up the seedlings, eighteen to twenty nuts were found, in different rows of the plantation, in various stages of germination, the radicles being from one-quarter to three inches in length, all in a perfectly vigorous state. When found, the nuts were covered to a depth of from two to three inches.

Professor W. J. Beal has recorded * some observations which are interesting in this connection. In addition to a number of weed seeds, deeply buried in sand for ten years and then uncovered in order to test their vitality, he mentions the burying also of black walnuts and Black Oak acorns at depths varying from a "few inches" to three feet. Some of the nuts and acorns within a few inches from the surface of the ground germinated the first season; all the acorns at a depth of eight inches to two feet were decayed; a few acorns at a depth of two to three feet were found to have germinated, and the aborted plantlets were still alive at the end of nearly four years.

Fig. 17.—View in the forest on the bottom-lands of White River, Indiana.—See page 101.

As a rule, the mature fresh nuts of the Hickories and Walnuts planted in the fall, or, after proper care during the winter, planted in the spring, germinate during the first season, not "lying over" and germinating the second, as is sometimes observed with other less bulky forest-tree seeds (*Robinia*, *Gleditsia*, *Gymnocladus*, *Acacia*, *Fraxinus*, etc.).

In March, 1893, ten bushels of black walnuts were planted

But all of the black walnuts buried from eight inches to three feet deep were decayed, there being no indication of germination as in case of the acorns.

The greater ability of acorns to preserve their vitality for a limited time in a quiescent or germinated state when deeply

* *Proc. Soc. Prom. Ag. Sci.*, 1889, p. 15.

buried was further well demonstrated in the planting of five bushels of Cork Oak acorns (*Quercus Suber*) by this Department in 1892. Through carelessness in planting—the acorns being plowed under contrary to instructions—many of them were buried to a depth of six to eight inches; and while a larger number were decayed at the end of twelve months, one in about every dozen was found to be either in a fresh state or with germination more or less advanced. The ascending axis was in no case, however, much developed, the main energy being exhausted in the production of large radicles.

Professor Beal does not state how many walnuts he buried, but presumably the quantity was small and, perhaps, not sufficient to indicate the retentiveness of vitality in the species which appears to be fairly well shown in the case of the Department plantation. The explanation of the long retention of vitality in the case of these black walnuts must, doubtless, be found in an accidental but proper adjustment of moisture conditions—dependent upon the season and character of soil—conditions which, in all cases, have much to do with the behavior of all planted seeds.

Department of Agriculture, Washington, D. C. *Geo. B. Sudworth.*

A Few Annuals.—II.

SWEET ALYSSUM is one of the best-known annuals for a front border, and it has a dainty beauty but is not as fragrant as its common name would seem to indicate. A dwarf form, Tom Thumb, has lately been introduced, and makes good compact-growing plants. The variegated Sweet Alyssum can only be increased by cuttings. Seeds of Sweet Alyssum planted in the open are quite certain to germinate, and the plant will often perpetuate itself by self-sown seed. There are several hardy Alyssums, mostly yellow, and these are excellent for borders; the best is probably *A. saxatile*, which in the early spring is cheerful and attractive. This sort may be bought of the hardy plantsman, as seeds do not germinate readily.

Candytuft (*Iberis*) is a hardy annual, which may be sown in the fall in a warm garden. This flower, in its shades of white and mauve, is pretty in the borders, but only one crop of these is produced, and this is soon over. As these flowers are in umbels, they are not especially useful in floral arrangement. The hardy Candytufts are easily established, and are among the best of trailing, half-shrubby perennials, bearing flowers of the purest white for many weeks.

The Balsam, *Impatiens*, is one of those plants concerning which every seedsman takes especial pride in declaring that his strain is sure to produce double-flowered kinds. With all their beautiful pure colors and their old-time associations they appear to me unpleasant plants owing to their fleshy stems. One of the prettiest bedding effects I have seen was made with *Impatiens Sultani* with a border of silver-leaved *Centaurea*. This *Impatiens* requires warmth and careful treatment of the seed, though it is easily increased by cuttings.

The single annual Chrysanthemums are pleasing plants in the garden, although the flowers and foliage are rather soft for cutting. The flowers are mostly yellow or creamy white, with dark eyes. The plants are thrifty, and one and a half to two feet high, and continuously in flower.

The annual and biennial Larkspurs require less space than the hardy perennial kinds, but the latter are so much more effective that the annuals and biennials are not much valued in gardens now. I seem to have omitted Forget-me-not, *Myosotis*, from both of my former lists, but I should not forget to give it a place in my garden. The Forget-me-not is not only a flower of sentiment, but of dainty beauty. It is of the easiest possible culture. None of the varieties are prettier than *M. palustris*, which has escaped from cultivation, as the botanists say, and is now found at home in moist places everywhere. It is, however, a rather sprawling species, and for the garden *M. dissitiflora* is one of the best. *M. alpestris Victoria* is also a fine kind, very compact and floriferous, but with short stems. Although Forget-me-not requires much moisture, this should be at the roots, and not near the leaves, which rot if exposed to wet. Their small shining black seed germinate readily, but the seed-bed should be shaded.

One cannot have a complete old-fashioned garden without Four-o'clocks, *Mirabilis*, with their sweet-smelling flowers so strangely opening to greet twilight wanderers in the garden.

Nicotiana affinis is a hardy annual which will perpetuate itself in the garden from self-sown seeds. It is a tall noble-appearing plant, with leaves decreasing in size from the base upward. The large white flowers, with long tubes, open in the early evening, and are pleasantly fragrant. They remain open until the middle of the morning, and are capital for even-

ing decorations. This is one of the last annuals to be cut off by frost.

Few packets of seeds will make a greater show in the garden than one of Petunias, and once established they will be happy there, for they are hardy annuals, great seed-bearers and every seed seems fertile. Perhaps the best all-round Petunia is the large-flowered white, which is apparently a distinct species. This is not only a good garden plant, but will do well in the house, where its fragrant flowers are very satisfactory. There are many bad faded colors among the Petunias, and they need careful culling. The Countess of Ellsmore was a great gain for a pure rose-color, but lately a new strain from California, of very large, curiously marked, fringed flowers, promises to supersede the old kinds. A strain of large-flowered, double Petunias has also become fixed, but to many persons these flowers, from their confused and lumpy character, are hardly worth growing.

Calendulas, Pot Marigolds, have already been mentioned, but there is another pretty kind of these known as *C. fluvialis*, which bears a single white flower with brown reverse. This is well worth growing, though of weedy habit, and, like all single Calendulas, closing at night or during cloudy days.

Phlox Drummondii is a pretty as well as popular annual in a great variety of colors. It is most effective in the garden when planted in separate colors, beds from seed mixed haphazard having no consistency or meaning, and are moderately useful for cutting. The general effect of these plants, unless they are well grown, is ragged.

Portulacca will thrive in dry borders in full sunshine, where few other plants will survive, and are certainly showy, though there is always a suggestion of Pusley attached to them. They are tender annuals, and the seed will not germinate without considerable heat.

Salpiglossis has curiously shaped and oddly marked flowers, not very showy or pure in color. One season's trial of this plant will satisfy most gardeners.

Spherogete speciosa is an old annual, not as generally grown as its merits deserve. It is a yellow composite, with narrow ray florets, and the plant is of neat habit. Objection may be made that yellow-flowered composites are very plentiful and one would preferably grow those which are of the readiest culture; still *Spherogete* offers no difficulty, the seeds germinating readily.

Ten Weeks Stocks are great favorites in some gardens and with some florists, the double sweet-scented white flowers being lasting and useful for floral work. But there is a suggestion of lumpiness about the flowering plants, both in the garden and when used for bouquet work. Seeds of fine double Stocks are apt to have delicate germinating powers and they require careful attention to make them germinate.

Swan River Daisies are small plants with delicate, finely cut foliage and small blue flowers, which I always enjoy seeing in the garden. They are pretty in a front border and are sometimes useful in a delicate floral arrangement. In spite of their almost minute habit they are easily grown and the seeds germinate readily in the border.

Bulbs for Spring Planting.

AMONG bulbous-flowering plants for spring planting, the Tiger Flowers are an important group. Those most commonly offered by American dealers are varieties of the Peacock Tiger Flower, *Tigridia pavonia*, a native of Mexico. Among the varieties are *Grandiflora*, *Grandiflora alba*, *Conchiflora*, *Speciosa*, *Grandiflora rosea* and others. The three most distinct varieties are *Grandiflora*, in which the leading color is crimson; *Grandiflora alba*, principally white; and *Conchiflora*, orange-yellow. There are other intermediate forms in which these colors vary, all of them very beautiful. Indeed, it would be difficult to imagine a variety of the Peacock Tiger Flower that is not beautiful. The flowers of these, as of all *Tigridias*, are short-lived, but they continue to come, day after day, and under favorable conditions until autumn frosts kill the buds. One great point in favor of this class of bulbs is that they are cheap. They increase fast by division, and even as far north as Vermont, when the frosts hold off late in the autumn, they mature sufficiently to be wintered and flowered the following year. They need to be kept in a warm dry place; in a cellar they generally decay before spring. The soil best suited to these bulbs is a warm sandy loam, with good drainage. They need plenty of moisture until after flowering, and in a dry season this must be artificially supplied. The bulbs should be planted deeper than most bulbs of their size.

Other species of *Tigridia* are cultivated, but they are not so striking or showy as these. *T. Van Houttei* has lilac and pur-

ple flowers, a little more than an inch wide, borne in great profusion, not rarely thirty flowers from a single bulb. This species is one of the easiest to grow, but the flowers are not very striking and make a poor showing by the side of a variety of *T. pavonia*. The flowers of *T. Dugesii* are still smaller, and scarcely an inch wide; they are nearly white, tinged with violet or purple.

One of the most desirable of the smaller bulbous plants of this class is what is sometimes called *Tigridia Herberti*, but which, though of the same natural order, is not a *Tigridia*, but a *Cypella*, a native of Buenos Ayres. It closely resembles the Tiger Flower and thrives nicely under the same treatment. The flowers are an inch wide or more, yellow, varying from light to a darker shade, and the plant is increased by division.

Until last season I found *Bessera elegans* a difficult bulb to grow. The trouble was in the drainage. It needs a light loamy or sandy soil and the driest possible place. I doubt if it is possible to give this plant too dry a place. Of course, it needs to be reached by rain, but the moisture should drain off as fast as possible. In such a place I had perfect success, and the bulbs were monsters as compared to the collected ones. It blooms earlier than the Mexican Star Flower, *Milla biflora*, and is, on this account, more sure to ripen in our shortseasons.

Milla biflora has bulbs similar to those of the *Besseras*, but the plant is quite unlike it in many ways, and although the scarlet drooping flowers of *Bessera* are pretty, the much larger pure waxy-white ones of the *Milla* are, to my mind, much handsomer. They are more durable, and on long, naked stems well suited for cutting. The *Milla* is not so difficult to grow, and any good garden-soil will suit it.

Notes on Violets.

WITH the lengthening days and increasing sunlight, Violets grown in cold frames are now blooming profusely; the flowers are much superior in quality to those produced after this time in greenhouses, as these are now coming small, pale and showing signs of exhaustion. As the time for severe frost is probably past, the leaves which have been packed round the sides of the frames can be removed and utilized in making hot-beds; it will not be safe, however, to dispense with mats and shutters, in this latitude, at least, before April 1st. More frequent waterings will now be found necessary. Violets are more often injured by too little than by too much water. A little liquid-manure can advantageously be used; an application once a week during the remainder of the flowering season will be helpful. As the midday sun is now strong, some shade should be given to the plants for a few hours every day. Lath shadings are good for this purpose, but if these are not at hand a light coating of lime-wash should be applied to the glass. This shading keeps the plants cooler, and Violets dislike a high temperature. We find that the flowers come of a deeper color and last much better when grown in shaded frames than when exposed to the direct rays of the sun. Air must be freely admitted, for no plant resents coddling more than the Violet. Runners are now being produced quite freely; the best of these can be taken off and dibbled quite thickly into boxes of sandy compost, care being taken to secure stock from the healthiest and most vigorous plants.

Lady Hume Campbell is not a satisfactory winter bloomer in cold frames with us, and it appears to require more heat than Marie Louise, which blooms freely all winter long, and up till March 1st had given ten times as many flowers to plants as the Lady Campbell; the last-named sort is now flowering abundantly. As grown by Mr. H. Nuebner, of Groton, Massachusetts, this variety is superb, and with most growers it has been a success. It cannot be called disease-proof, however, as we have during the present winter seen two or three establishments where it had been quite wiped out by the leaf-curl.

Where Marie Louise can be grown well it is still ahead of all its competitors. The new Farquhar promises to make a strong bid for popular favor. Some three weeks ago I visited the greenhouses of the Messrs. Farquhar, in Roslindale, Massachusetts, to see the new variety at home, and looking over the whole stock saw no trace of disease. Every plant seemed in perfect health; the flowers were of good size and borne on long stems. The color is similar to that of Marie Louise, although the distributors of the plant claim that it comes even darker. It more nearly resembles Marie Louise than Lady Campbell, although it seems quite distinct from both in habit when a batch of the two is seen together. Mr. Farquhar pointed out a number of plants of their new kind planted among the diseased stock, which were perfectly clean, and yet we have no idea that it will be proof against disease.

Among single Violets it is still hard to beat the Czar. One or two other kinds produce a few more flowers, but they are of greatly inferior quality. Wellsiana is a fine kind, but produces runners sparingly, hence is increased slowly. The new California will be quite extensively planted next fall; so far as we can judge from flowers on young plants received, it is very similar to the Czar, but if it produces flower-stems of the size and quality claimed and proves a satisfactory winter bloomer, it may eventually supplant that good old variety.

W. N. Craig.

New Grapes.

THOSE who are looking for new grapes of high quality may safely select the Alice, which keeps well in common storage until March. It resembles Diana more closely than any other grape I know, but the color is more like that of Catawba. The flavor is sweet, and the skin lacks wholly the unpleasant tang left by Catawba. In the size of cluster and in general appearance Alice is much like Delaware, but the berry is fully as large as that of Catawba. The skin is tough, and dries like that of Diana, without rotting, and the grape is sugary, qualities which suggest that it would make good raisins. The seeds are small, and there are not many of them. It ripens about September 20th to September 30th. Growers of this Grape report that the wood is hardy and matures well, and that its foliage is heavy and the canes strong.

Mr. George C. Campbell, of Delaware, Ohio, the veteran Grape-grower of the United States, has a seedling which ripens early, the grapes being large and black. This new sort has not yet been sent out, but one more really good Grape may safely be counted upon.

Of the Concord seedlings and other recently introduced early or late white sorts, Colerain seems to me the best. It is one of the earliest, ripening about the last of August. It has few seeds, and these are small, and medium-sized bunches of good-sized berries. The color is greenish white, with a fine bloom. The vine is a strong grower, and it is altogether hardy.

Points which all new Grapes should include are short-jointed wood, berries of good size, adherence to the stem after ripening, small and few seeds, uniformity in ripening. Of course, quality and quantity will be demanded. An otherwise excellent Grape, the Diamond, is lacking in uniformity of ripening, and it is altogether uncertain whether it will mature by September 10th or not until a month later. Many of Rogers' seedlings are, like Lindley, too long-jointed.

Clinton, N. Y.

E. P. P.

Early Flowers.—The winter season just closing was remarkable in this locality for continued low temperature. From Christmas until the end of February there was seldom even a superficial softening of the ground on sunny days, and there were no nights without a freezing temperature. Under these conditions winter flowers made no progress, and Snowdrops, which were showing color in the middle of December, made no advances until the slightly rising temperature of the first days of March allowed them to expand. Now Snowdrops are daily becoming more plentiful, and the first of the Scillas are showing color, while the earliest Crocuses are in bud.

The Snowdrops in flower at present are *Galanthus imperati*, Atkins' fine variety, and forms of *G. Elwesii*. The newer forms, *G. Aidin*, *G. Cassaba*, *G. globosus* and *G. unguicularis*, are as forward to flower as the type. The scorching cold has burned foliage not affected in ordinary winters. The leaves of Oriental Poppies have been cut off, and Primulas are mats of brown leaves. Some of the early Irises have lost their foliage, while others are fresh and untouched. The vagaries of frost are past finding out.

Elizabeth, N. J.

J. N. G.

The Columbian Raspberry.—From my experience with the Columbian Raspberry I have found that the stalk is sometimes as large as a stout staff and the general growth is very luxuriant. The fruit is more dry than that of the Schaffer, and will both ship and can better. It is more nearly a purple than a red raspberry, but the color is brighter than that of Schaffer in the dried berries. The yield is enormous. It is unquestionably a cross of Blackcap and Red Raspberry parents. My seedlings of Schaffer almost all came black, and they are subject to the same disease that affects our black Raspberry—an anthracnose—the same disease which put an end to growing the purple Rochelle and which threatens to kill out the Schaffer. It is a mistaken prejudice with the majority of buyers to prefer red raspberries for all uses, but for home use I think the Columbian a decided acquisition.

The Gypsy Moth in Massachusetts.

To the Editor of GARDEN AND FOREST:

Sir,—This statement relates to about thirty-three acres of land in three separate parcels, all located in Medford, Massachusetts, and in the section described by the Gypsy Moth Commission as infested. It is about three-fourths woodland, with the remnant well sprinkled with Apple and shade trees.

Finding that all his force would be likely to be fully occupied elsewhere, the field superintendent kindly gave me permission, last spring, to take charge of this land myself for the purpose of suppressing and preventing the multiplication of the moths upon it, and, if possible, exterminating them. For this purpose a good supply of burlap and creosote-oil was given me.

The work has been done at odd times by myself, my daughter and a hired man; and we are satisfied with the result as evidence that the gypsy moth, like most other noxious insects, may be reduced to harmless proportions, at small expense, by all private land-owners who choose to attend to the matter for themselves. Indeed, the expense and trouble is so small, and the result so satisfactory, as to prove that it would seem a simple waste for the state to be at further expense, and cause much private annoyance, by continuing the work of the commission with the aim of absolute extermination, instead of confining its efforts to the suppression of the insect from year to year on public grounds, in coöperation with their custodians, and on neglected private premises, besides the reasonable inspection of private grounds cared for by the owners, with their knowledge and in their presence, or that of their authorized agents.

We destroyed from 10,000 to 12,000 caterpillars in their season, and have since found and painted with creosote-oil about 115 patches of eggs. Fully half of these were under stones on the ground, and nearly all could be reached without climbing. Some ground now covered with snow is yet to be searched. While it is very improbable that no bunch of eggs has been missed where search has been made, it is very certain that those missed are too few to be a material harm. Not a tree or bush on our premises was noticeably stripped of foliage by the moth during the season. No trees were burned, marked or marred by them, and all burlap used was taken down and burned at the close of the season. We have enjoyed the privilege of helping ourselves, and hope we may be allowed to enjoy it in future.

The commission, as a branch of the work of the State Board of Agriculture, has a permanent use and value, especially if clothed with enlarged powers to cover all sorts of rapidly multiplying, and therefore noxious, insects. But we believe that function should be exercised in harmony with private-wishes, but never in private grounds except at private cost.

Medford, Mass.

Walter C. Wright.

The Meeting of the American Carnation Society.

To the Editor of GARDEN AND FOREST:

Sir,—Allow me to add some notes to your account of the meeting of the Carnation Society in Boston. The first thing to strike the visitor was the large proportion of recent varieties in the exhibition and the absence of the old kinds. The object of the raisers and growers seemed to be primarily a stiff stem and, by means of disbudding, large flowers, but the lack of a good stem outweighs every other good quality, and, therefore, many of the old sorts, no matter how beautiful they may be, unless they yield abundantly and are borne on strong stems, have little chance in the race. And, really, this is a proper line of selection. Objection has been made to the practice of disbudding, and there are æsthetical people who would rather see smaller flowers and the buds remaining as they are in nature, but, after all, a Carnation cannot be made ungraceful even by extreme disbudding, as a Chrysanthemum can be when similarly treated. Among the whites old varieties are practically gone. Mrs. Fisher and Lizzie McGowan are comparatively recent, but they are grown only in the east and in separated districts. Silver Spray is the favorite white of the west. Anna Webb still holds a leading position among the crimsons. Jacqueminot and the Stuart (red) were not shown well, even by their introducers, but they both have the great advantage of a good stem. Among the scarlets I still like Portia, because of its healthy abundant bloom and its perfection of form. It has the demerit, however, of being small. A scarlet Carnation with a flower as large as that of Hector, but

with all the other good qualities possessed by Portia, would be an acquisition. As far as simple flowers were concerned Hector was pronounced the best scarlet exhibited, but it has the great defect of a feeble stem. The striped Helen Keller, unique in its class and magnificent in its form, is not only a Carnation of the best type, but it stood the test of two days' exhibition better than almost any variety in the exhibition. It was whispered that these flowers were cut before they were quite matured, and this may account, to some extent, for its holding so well. If this is true, why should not exhibitors act upon it? Some may have failed because in their anxiety to secure the fullest development of their flowers they allowed them to remain on the plant too long. The eastern exhibits went down badly on the second day. It was held by some that this was caused by overfeeding. These are points certainly worth studying and settling.

The old yellows are out of date, and such varieties as Buttercup and Bouton d'Or are the principal ones grown. Success with each of these depends much on local and special conditions, and there are a few growers who have mastered these conditions so well that they have the field almost to themselves. Many good Carnation growers find these varieties hard to propagate. President Dailedouze starts his plants early and gets a long season's growth, and from my experience this seems a good way to treat all yellow-flowered Carnations. The Buttercups exhibited by Mr. Southworth, and the Bouton d'Or by Mr. Dailedouze, were certainly remarkable.

The seedling table, devoted to varieties not yet distributed, was always surrounded by growers who came to select novelties. Every one must agree with what was said by the President about the advantage of having plants as well as cut blooms exhibited, for, otherwise, it is impossible to get at the character of the varieties. Storm King was the best white, in my opinion, although it is not very fragrant, but Alaska had many admirers, and those who have seen it growing declare it has all the qualifications of a good commercial variety. The flower is good in form, with a good calyx and stem, and pure in color and very fragrant. Della Fox looked promising the first day, but it folded badly on the second. It is of the most delicately shaded salmon-pink in the way of Daybreak. Triumph was a most promising new pink, resembling its parent, William Scott, and it stood the test of two days' exhibition even better than that good plant, and it had a better stem. Sylphide, a delicately tinted pink, also stood up well. Lena Saling was the best rose-pink on the first day, but it wilted on the second. Isabella Hunnewell, red-striped on a yellow ground, attracted much attention on account of its distinctness. The purest yellow shown was Henrietta Sargent. The flower is slightly undersized, and so far the plant has not been very productive. Eldorado, a picotee-edged pink, on a yellow ground, was, to my thinking, the handsomest in this class. It was finely fringed, which is an important qualification, and it stood the heat well, although it has not the best of stems. If a stem can be too good, Jubilee has this drawback. The stems of some of the flowers were so strong as to be rigid and ungraceful. It is an exceedingly bright scarlet, although the flower has not the best of forms. Perhaps the most distinct seedling of all was Maud Dean, which is quite a new departure, the petals being suffused with a color which may be called violet, deepening to the base. The form is perfect, and it lasts well.

By the way, the second prize for the best hundred white flowers was won by a seedling of Mr. Nicholson, and not of Mr. Chitty, as stated in your last week's report.

R. A.

The West Coast Spring.

To the Editor of GARDEN AND FOREST:

Sir,—While the days are growing longer and February is relaxing its icy hold on the Atlantic states, the West Coast is in the full tide of its growth and beauty. Broad fields of grain stretch away in billows of green—not the dark blue green of New England grain-fields, but a bright sunny green born of a kinder climate. The uplands are wrapped in varying shades, from the almost golden-green of the pastures and wheat-fields through the deeper tones of the Laurels and Bays, the still darker ones of the Live Oaks, up to the dusk of the thickets on the mountain sides. The deciduous trees are putting forth their tender leaves, wild flowers are everywhere and in every color, and give tint to the whole landscape. In the orchards the Almond-trees are all shimmering with a mauve-colored veil of blossoms, the Peach-trees are beginning to open, and brown buds of Plum, Prune, Cherry and Pear trees are swollen to bursting, while among the trees the ranchmen are turning up

red furrows and cattle stand knee-deep in clover. Through open windows we look across the broad Santa Clara valley, where occasional gleams of white show the clustered buildings of the ranches, with the steeples of the town of San José, ten miles to the north-east. At the further rim of the valley is the line of the foothills with their varying opalescent colors as the shadows of the clouds chase over them, and above these are the ragged peaks of the Coast Range, with Monte Diablo, dim and cloud-like, fifty miles to the northward. While we read of the wild weather of the east, stormy seas and snow-covered earth, we have balmy air and singing birds and blossoming flowers in the most delightful season of the year on this coast.

Los Gatos, Calif.

The Preservation of the Colors of Dried Flowers.

To the Editor of GARDEN AND FOREST:

Sir,—In your issue for March 6th I notice your London correspondent's remarks on the drying of flowers by means of heat, in order to preserve their colors. I can thoroughly endorse the utility of this method, as I have used heat for all dryings which I have made, and with most satisfactory results. I struck upon the idea quite accidentally some seven or eight years ago.

New York.

Leonard Barron.

Flowering Branches of Viburnum lantanoides.

To the Editor of GARDEN AND FOREST:

Sir,—On one of the coldest days in February I received a package by express, and after the removal of several layers of thick paper, masses of large showy flowers were found carefully wrapped in cotton, and suggesting that it was summertime somewhere. At first I thought of the Flowering Dogwood, but when they were fully uncovered I recognized them as the large cymes of the Moosewood or Hobble-bush, *Viburnum lantanoides*. The summer and autumn aspects of this tree are very familiar to many persons, but as its flowering-time is in late May, the flowers are not so generally known. This plant was figured in GARDEN AND FOREST, in vol. ii., page 535, and is there described as the handsomest of the native American Viburnums, and one of the most beautiful shrubs of our flora. The flowers I had received came from Cherryfield, Maine. The bare twigs had been cut and placed in water and set in the house for a fortnight, when they expanded into the flowers which I had received. No attention was given them except to remove them from the direct rays of the sun in the middle of the day. I have often seen branches of our spring-flowering ornamental shrubs and fruit-trees coaxed into bloom after this fashion, but certainly nothing of the kind equals in effectiveness this native wilding, with the hydrangea-like corollas of the neutral flowers on the margin of the cyme an inch or more across.

Andover, Mass.

A. S. D.

Recent Publications.

/ *The Wild Garden*. By W. Robinson. Illustrated by Alfred Parsons. Fourth edition. London: John Murray.

In the preface to the new edition of this book, which has become a classic among those who are interested in naturalizing hardy plants from other countries, the author tells us that it is more than twenty years since the first edition saw the light. He adds that during all these years his experience has gone to confirm his faith that where the original purpose of the book is carried out with due regard to soil and other surroundings of the plants, the open-air gardens of England may be made more artistic and delightful. The Wild Garden, as it is understood in this book, is not a careless and neglected tangle, nor is it the result of sowing the seeds of annual flowering plants in a haphazard mixture. Its controlling idea is the introduction of the plants of other countries which are as hardy as the hardiest of native common flowers in places where they will flourish without further care or cost. It has, therefore, nothing to do with what is often called a "wilderness," nor can it be confused with a picturesque garden, nor does it interfere in any way with the regulation flower garden. Judging from his own effort and experience, Mr. Robinson has achieved his highest success in the establishment of early-flowering bulbs in the turf of fields mown for hay, where, without interfering with the value of the crop, blue

Anemones, Snowdrops, Dogtooth Violets, Fritillarias, Wild Honeysuckles and Tulips bloom in the most natural way and have the most effective setting. The mountains of central Europe, Greece and Asia Minor furnish plants which blossom earlier than those of England, and, therefore, in warm soils which are sheltered by groves and banks of evergreens, the meadows which stretch about nearly every English country house can be made bright with early bloom. But the book deals as well with native flowers, and one of its most delightful chapters is that on British wild flowers and trees. But there is no need of enumerating or characterizing the contents of a book which is, perhaps, as well known as any other work on ornamental horticulture in the language. The very names of the chapters are suggestive of the wildness and freedom and natural charm of the scenes which Mr. Robinson describes and of the compositions he suggests. The art of Mr. Parsons is always delightful, and all his illustrations are engraved on wood, and have an effectiveness and finish which can hardly be excelled in works of their class. Mr. Robinson promises that in future editions some ideas of the book, which are as yet only in the type, may be seen more clearly in new illustrations, so that the reader may gain a clearer knowledge of what the author means when he speaks, for example, of the possible beauty of hedgerows and grass walks.

Of course, many of the cultural directions do not apply to plants in our climate, and many of the plants which thrive in English gardens would never become naturalized here. Nevertheless, the pictures and the text are both instructive and stimulating, and will suggest experiments which cannot fail to bring pleasure and profit to any one who undertakes them.

Notes.

Sunday last was the first really spring-like day of the year in this vicinity, and under its genial sunshine some of the Crocuses expanded for the first time. *Crocus Imperati*, the most robust of those we saw in a small collection, had fully opened its rosy purple segments and yellow anthers, while *C. biflorus*, equally early, but not as showy, was quite attractive with its lilac and white segments and orange-colored anthers.

The Sweet Pepperbush, *Clethra alnifolia*, is an excellent native shrub with a peculiar value, from the fact that it shows its long spikes of pure white flowers and yellow anthers late in summer, when it has few rivals in the field. In the last number of *Meehan's Monthly*, one of these shrubs on the editor's home grounds is described as fifteen feet in diameter and twelve feet high at the age of twenty years. With the delightful fragrance of its flowers, in addition to their beauty and attractiveness to honey-gathering insects, it is a charming ornament in its season.

Catawba grapes from New York state may still be had in fair condition, a five-pound basket costing twenty-five to thirty cents. Almeria grapes continue moderately plentiful, and sell at thirty to fifty cents a pound, the pink-tinted fruit bringing the higher price. Hot-house grapes are always scarce in February and March, and the only fruit of this class now to be had here are small lots of Gros Colman from Belgium. These bring the fancy price of \$3.25 a pound, but their dry stems and the tendency of the grapes to drop indicate the approaching end of their season. Black Hamburgs from Rhode Island are usually the first hot-house grapes seen here in the spring, and these will not be on the market before the first week in April.

The scale insects have not been very troublesome heretofore in the northern and eastern parts of the United States, but one of them has appeared in New York orchards, attacking Plums and other trees, and threatens to become a serious enemy. It may have inhabited certain orchards in small numbers for some time, but it never caused any alarm until within two years, and now it threatens the total destruction of thousands of trees. Mr. Slingerland, of Cornell University, has been making a study of this insect, and, although its life-history is not yet thoroughly understood, he has discovered enough to enable him to state that it can be destroyed by persistent spraying before spring growth begins. In an illustrated bulletin just issued by the Cornell Experiment Station, Mr. Slingerland explains how it can be distinguished from the San

José scale, and gives directions for treating the trees with the kerosene emulsion, so as to prevent it from getting started in April. The bulletin will be of great use to those whose trees are infested with this new pest if they will heed its instructions.

At the late meeting of the Carnation Society, in Boston, President Dailedouze stated that the cutting-bench fungus was more likely to appear when the benches were made of old boards. All the woodwork should be treated with a coat of warm lime before it is used. It was also suggested that sand more than two or two and a half inches deep was likely to harbor this fungus, since it did not dry out quickly. Mr. Chitty warned propagators against using the sand a second time, and other members stated that when it was necessary to use the sand over again it should be drenched with water which contained a minute proportion of carbolic acid. A solution of copper sulphate of the strength which is used in spraying would be equally good.

The last number of *The Gardeners' Chronicle* contains a good picture of the variety of *Doronicum plantagineum* known as *Excelsum* or *Harpur Crewe*, and recommends that after flowering in spring these plants can be taken up and planted in a reserve garden, so as to give room for other plants. We have often commended these hardy perennials for their beauty, and they have the advantage of being taller than most plants which flower in this season, and their large golden yellow ray-florets make very conspicuous objects. Plants of many of the *Doronicums* taken up in autumn and potted can be had in fine flower during late winter and spring, and if started in a cold frame even now they will make good decoration for the conservatory later on.

Professor Wiley, Chemist of the United States Department of Agriculture, has been making some investigations as to the possibilities of Sweet Cassava as an agricultural crop in the southern states, and he pronounces that it can be grown with safety and profit in the peninsula of Florida, and probably in the coast region of the other Gulf states. It contains so little ash and nitrogen that it will produce in poor sandy soils four or five tons to the acre, and the fresh roots will yield twenty-five per cent of starch of a high grade, which can be used as a substitute for the starch of Maize. A superior tapioca can be prepared from the plant, and so can glucose, and it furnishes an excellent food for man and for cattle, although it is deficient in albumen. To make a well-balanced ration for cattle it should be mixed with one-fourth of its weight with cotton-seed oil cake.

Professor Budd, of the Iowa Agricultural College, writes that he fears the losses to the Orange groves of Florida are even more serious than has been stated. Of course, the present crop is all gone, but the fact that many of the Orange-trees remained leafless after deciduous trees had come into leaf seemed to indicate that they have received a severe shock. If cut back, Professor Budd thinks, they may start from the stubs, but their vitality may be too low to give paying crops of fruit. He adds that the trees which were cut back by the frost of 1886 have never paid for the space they occupied, and that many of them which did come into leaf the next April died during the following summer. Of course, time alone will reveal the full effects of this disaster and enable us to calculate the total loss. We hope, however, that Profesor Budd's view of the case will prove too gloomy.

When Layard first uncovered the ruins of Assyria he identified, among their sculptured ornaments, representations of grape-bunches, pomegranates, reeds and apples, and, with regard to the prominent objectso frequently held in the hands of the chief figures portrayed on the bas-reliefs, he wrote that he "would not hesitate to identify it with the pineapple unless there were every reason to believe that the Assyrians were unacquainted with this fruit," and he added, "the leaves sprouting from the top prove that it was not the cone of a Pine-tree or Fir." As it is now well known that the pineapple is of American origin, Layard's doubt upon this point is confirmed; and Dr. E. Bonamia, in his recently published *Flora of the Assyrian Monuments and its Outcomes*, asserts his belief that the symbol represents a Cedar-cone, which was used in religious and royal ceremonials to sprinkle holy water. Illustrating his words with reproductions of the ancient sculptures, Dr. Bonamia also claims that he has identified among them figures of the Date-tree, the pomegranate, the fig, the banana, the Pine-tree, the melon, the Reed, the Lily, the Baobab and some daisy-like plant. But, perhaps, the most interesting of his suggestions is the one he makes with regard to the origin of that ornament, so familiar in heraldry and decorative

art, which we call the fleur-de-lis. It has never been well established that this ornament was evolved, as its name implies, from an Iris-blossom ; and Dr. Bonamia thinks that he has traced it back, not to any other flower, but to the Assyrian custom of tying a pair of horns to a Date-tree as a charm against evil spirits. Representations of these "luck-horns" are frequent on Assyrian monuments, and Dr. Bonamia argues that the way in which they are attached explains the origin of that fillet or cross-band, so conspicuous in the ornament called the fleur-de-lis, which, of course, has no prototype in the Iris or any similar flower.

Botanical science has sustained a fresh loss in the death of Mr. John H. Redfield, which occurred at his home in Philadelphia, February 27th. Mr. Redfield was born at "Middletown Upper Houses," now Cromwell, Connecticut, July 10th, 1815, and had nearly completed his eightieth year. He came from a pure New England ancestry, John and Priscilla Alden being among his progenitors. His father, William C. Redfield, at the birth of his son a country storekeeper, was a man of much more than ordinary intelligence, who became in after years a noted meteorologist, and made important discoveries in regard to the rotary and progressive movements of storms. The elder Mr. Redfield looked well to the school facilities of his district, and here the son's education was commenced. It was continued at Stamford, Connecticut, at the High School in New York city, and finally at a private school. While at the school in New York, to which city his father brought his family in 1824, a teacher strengthened his inherited love of scientific pursuits, by taking him with him in his country walks and instructing him in mineralogy. In this way also he acquired the love of botany, which distinguished him later. In the interval between his attendance at the different schools he heard Dr. Torrey's lectures on chemistry. In 1836 he became a member of the New York Lyceum of Natural History, and this intensified his boyish interest in the sciences already named, besides developing in him a taste for conchology. At this time, Dr. Asa Gray was librarian and superintendent of the Lyceum, and here began the friendship which became closer with passing years, and continued through life. In 1843 he was most happily married, and in 1861 he removed to Philadelphia to take a position in the large car-wheel works of A. Whitney & Sons, his father-in-law being the head of the firm. During these years his spare time was given to scientific pursuits, especially to botany, in which the order Filices was his favorite. He had been elected a member of the Academy of Natural Sciences in 1846, and now became a life-member. In 1876 he was made a member of the Council and Conservator of the Botanical Section, and in 1879 Corresponding Secretary of the Conchological Section. A member of the Publication Committee in 1877, he became chairman in 1891. All these offices he held until his death. Retiring from active business in 1885, all his leisure time, when in the city, was devoted to the Academy, and more particularly to the botanical section, where, in the face of many obstacles, he accomplished a great work in the rearranging of the vast herbarium and in the proper mounting of a great part of it. During this period his summers were mostly spent on Mount Desert Island, the flora of which he studied in connection with Mr. Rand, the result being the excellent catalogue recently published by them. Mr. Redfield's published articles number fifty-four. Of these, forty related to botanical subjects or to botanists, twelve to conchology, one to meteorology and one to fossil fishes.

As a scientific man Mr. Redfield was held in high esteem by the leading botanists of the country. His friendship was sought and cherished by such men as Doctors Torrey, Gray and Engelmann and their successors. He was of great assistance to them by the excellent judgment he displayed in the notes he made upon the plants contained in the very important herbarium under his control, and in forwarding portions of them for inspection. The Academy of Natural Sciences will keenly feel the loss of his faithful and efficient services and of his many gifts of important sets of specimens ; and not the less, his wise counsel in its ruling board. In botany, his name is commemorated by a beautiful grass of the western plains, the *Redfieldia flexuosa*. Mr. Redfield was of most genial and kindly address. No one gave a warmer or more sincere greeting to a friend, or showed better, on all occasions, the spirit of a true Christian gentleman. Honorable to the last degree, generous and kind in every relation of life, he was yet modest in character and diffident of himself. He was almost the last remaining of the old set of botanists, among whom he was honored as an associate and loved as a friend.

Sculpture in Garden Art.

DURING the month of May an artistic spectacle of a novel sort will be set before the people of New York. The National Sculpture Society will then hold its second annual exhibition in the spacious galleries of the Fine Arts Building on Fifty-seventh Street. It will not be confined to works recently produced, or to American works exclusively, but will include a retrospective collection, and, therefore, even as regards the sculptor's art alone, will be novel and ought to be exceptionally attractive. But the most interesting announcement is that the purpose of the exhibition will be "to show the possibilities of combining sculpture with flowers and plants in both natural and formal gardening and in interior decoration." To this end the services of Mr. N. F. Barrett, landscape-engineer, and of Mr. Thomas Hastings, architect (of the well-known firm of Carrère & Hastings), have been secured to prepare the designs for the arrangement of the galleries and to superintend their execution, while Messrs. Pitcher & Manda will supply the plants which their schemes will require.

It is believed, the circular of the Sculpture Society adds, that the tendency of such an exhibition will be "to encourage a larger use of sculpture in the embellishment of the villas and houses of America, and to give a new and powerful impulse to the production of ideal sculpture throughout the nation." Both these aims are, indeed, worthy ones. Even cultivated Americans often regard the sculptor's art as valuable merely for the making of portraits or of monumental memorials in which portraiture plays a prominent part. They appreciate its peculiar commemorative utility, but either wholly ignore its role as a minister to the love of beauty, or consider this distinctly subordinate to what may be called its biographical function. Or, at the best, they admire classical works, consecrated by the verdict of time, and covet reproductions of them for private or public enjoyment. The cases are rare when the art, as practiced by living masters, is sympathetically approached from its purely aesthetic side. This is proved in our streets and parks, as well as in the interior of our houses and public buildings, although, as has been more than once said in these pages, even those classes of our popula-

tion which have the least education are quick to appreciate the fact if a commemorative statue is unusually successful from the aesthetic point of view.

In the time of our grandfathers a wider feeling for the beauty of statuary seems to have existed in this country. But the taste of that time was as childishly crude as its confidence in itself was childishly frank. Indoors the result was a profusion of foolish sentimental figures and models of Trojan's Column and the Leaning Tower of Pisa—often brought home as trophies from an Italian tour—of tomb-like, clumsily carved white marble mantelpieces, and of huge alabaster urns which looked like receptacles for the ashes of past generations—all being placed where it was supposed they would show to the most striking advantage, without much thought whether or no they would harmonize with their surroundings, whether or no they would increase or decrease the general beauty of the interior. And outdoors the result was urns and figures of the same sort placed in the same independent fashion, and accompanied, perhaps, by iron dogs or deer, wildfowl or wild beasts, supposed either to give dignity to the approach they flanked, or, more cunningly set amid the plantations, to afford the chance observer the high delight of a momentary belief in their vitality. As knowledge and taste have grown among us, puerilities like these have disappeared, or they survive only in isolated localities, or as piously preserved, with smiling tolerance, out of respect to some bygone kinsman. But, as yet, things of a better sort, disposed in better ways, have seldom come to take their place, and it is a place which should by no means be left empty. The sculptor as well as the painter should play his part in decorating and furnishing the interiors of our public and private buildings, and the sculptor as well as the landscape-artist and the gardener should help to adorn their surroundings. But in the one case, as in the other, two things should be considered: the intrinsic beauty of the sculptured work, and, in its character and its placing, its appropriateness to its environment. One of the most important lessons taught by the Chicago Fair was the noble decorative significance of the sculptor's art, and it was taught so emphatically because nowhere had the sculptor been allowed to feel that he could work in independence of his brother artists. Already we see the effect of this lesson in the increased amount and excellence of our architectural sculpture. And the coming exhibition, if artistically successful, may do much to assist us to a knowledge of the value of idealistic sculpture for outdoor use and of the proper ways of using it.

Fully to display the sculptor's decorative power, formal gardening schemes need great avenues of trees and great stretches of water, giving room for the introduction of stately or graceful figures in symmetrical array, for noble lengths of balustrading and fountains of monumental size. Nothing of this sort could, of course, be attempted within four walls, even were the vast interior of the Madison Square Garden to be the chosen area, and even did all the horticulturists in America contribute of their products. And with regard to naturalistic schemes the case is similar. In such schemes the sculptor can never play a dominant part, as he may in certain portions of formal schemes, and even his part as a docile assistant is rather narrowly limited, and should be played with the greatest care and discretion. Nothing is more certain to injure a naturalistic gardening scheme of broad character than the presence of the smallest piece of sculpture inappropriately placed; and, as the Parc Monceau, in Paris, proves, even Frenchmen have conspicuously sinned in this respect, admirably though they use works of sculpture in more formal pleasure-grounds like the Luxembourg and the Tuilleries Gardens. We note with regret, by the way, that the Sculpture Society's circular speaks of its exhibition as including "an exhibition of landscape-gardening." In art, as in everything else, it is important that words be used with precision, lest confusion of thought arise from verbal inaccuracy; and it would be a very confused thought,

indeed, that could picture the interior of an apartment transformed into any scene having a "landscape" character. Landscape-gardening is one branch of the art; naturalistic gardening on a small scale is another, with quite different ideals to meet as well as means to employ. No more than the latter branch, on its smallest scale, can be attempted in the coming exhibition, but, even so, right management will be still more difficult than with small formal schemes.

All this is said not to discourage in any degree the projectors of the exhibition, but to show them, rather, that the difficulties which they will meet will be appreciated by all observers who have thought about work such as they have in hand. It is a good sign that an architect, as well as a gardener, has been engaged to carry out the interesting conception of the Sculpture Society, for, in all formal gardening arrangements, architectural ideas must prevail, and to them both the gardener and the sculptor must accommodate himself. We wish these artists every success in their novel task, and bespeak wide public attention for their exhibition when its doors shall open, feeling assured that they will show us many things worth seeing in themselves, and, perhaps, some which will be of utility, as giving hints and suggestions, if not actual models, for the introduction on a much larger scale of more beauty and more variety into our public parks and the surroundings of our homes.

Honey Locust in the West.

THE Honey Locust has a much greater western range than the Black Locust, and it possesses many qualities that should make it a general favorite. It has been extensively planted, but has been used to a limited extent only. Indeed, so far as I know, its only use, except for fuel, has been as post-timber. The wood is hard and takes on a beautiful polish, while in color and grain it is much more attractive than several fashionable cabinet woods.

Repeated efforts to grow the Honey Locust at the Agricultural College of South Dakota failed. The young seedlings grew well the first year, but were killed, root and top, the first winter. In north-western Iowa, twenty-five miles north-east of Sioux City, there is a fine specimen of thornless Honey Locust, and in the grounds of the Iowa Agricultural College is the handsomest thornless Honey Locust tree I have ever seen. Its trunk is about two feet in diameter; the crown is round and well developed, with a spread of branches of about fifty feet across, and altogether it is a tree of great beauty.

Professor Silas Mason, of the Kansas Agricultural College, planted a quantity of seed of the thornless variety of the Honey Locust four years ago, and has a half-acre plat of trees from four to nine feet high. Not more than half the trees are free of thorns, and there is every gradation from smooth to very thorny specimens. These thornless Honey Locusts cannot be too highly recommended for lawn planting. They give a light, though sufficient shade, and their finely divided foliage and long brown fruit-pods make them very attractive.

On the dry uplands of western Kansas the Honey Locust is one of the most flourishing trees, as is proven by the fine growth of a plat of the species at Ogallah, where it surpasses the Black Locust in size. At Hutchinson, in the moist soil of the Arkansas valley, it also makes fine growth, thus proving its wide adaptability. Thrifty trees were seen in the suburbs of Denver, grown under irrigation. Honey Locust grows well throughout central and southern Nebraska. In an eight-year-old plat at Lincoln specimens twenty feet high were seen.

A number of years ago the Honey Locust was extensively tried as a hedge-plant, but it does not lend itself well to this use. It is too rampant a grower, and no amount of lopping, weaving, bending and pruning can keep it within reasonable bounds.

Washington.

Charles A. Keffer.

The European House Sparrow in America.

A VERY complete history of the naturalization of the so-called English sparrow, *Passer domesticus*, on this continent, together with some of the results of this introduction, was recently given by Mr. H. C. Oberholser, in a paper read before the Brooklyn Institute of Arts and Sciences. A condensation of the more important portions of this paper is herewith given:

The introduction into the fauna of any country of any foreign species is always fraught with the danger that the absence of natural checks will permit it to multiply with undue rapidity and develop destructive characteristics unknown in its home. There are certain species of birds, for example, which it is difficult to naturalize in another country, even when the conditions seem most favorable, as is proved by the frequent attempts to introduce the European goldfinch and the skylark into the United States. But when a species is found sufficiently robust to make itself at home under a new environment its very vigor will insure the development of many injurious propensities. If the persons who introduced the English house sparrow into this country had made inquiries among the farmers of Great Britain and Europe in regard to the reputation of this bird, they would have probably learned that it was hardly a safe species to colonize, having already shown what might happen by its destructiveness in Australia and New Zealand. The sparrow, however, never developed its full power for evil until it came to America, where its destructive effects have only been paralleled by the introduction of the rabbit into Australia and of the mongoose into Jamaica.

In the fall of 1850 eight pairs of sparrows were brought to Brooklyn by the directors of the Brooklyn Institute, carefully housed during the winter, and liberated during the spring. The shade-trees of Brooklyn and New York were then being defoliated by the caterpillar of the white Eugenia moth, and it was supposed that the sparrow would suppress this insect. These birds did not multiply fast enough, and in 1852 fifty more were liberated in New York harbor and a colony was placed in Greenwood Cemetery. From 1854 to 1858 sparrows were brought into Portland, Maine, and Peace Dale, Rhode Island, and in 1860 more were brought to New York and to Quebec. In 1867 eighty birds were liberated in New Haven, and in 1868 twenty were imported to Boston. One thousand were brought to Philadelphia the same year; forty were carried to Cleveland, and soon after they were transported from the eastern cities to San Francisco, Salt Lake City, Halifax and other places. Perhaps this widespread introduction was based partly on sentiment, because certain naturalized Europeans found in the chirp of the sparrow something which reminded them of their native land. But erroneous reports of the benefit derived from the presence of these birds in the cities where they were first imported made such a demand for them that it was cheaper to bring sparrows directly from Europe than to pay the price asked for them in New York city.

In the early years of their introduction the sparrows multiplied with even more than their natural rapidity because they were provided with food, shelter and nesting-places, and watched over with tender solicitude. They are subject to few contagious diseases, and their natural enemies are few. The northern shrike and the screech-owl are their only serious foes among birds, although there are others which attack them occasionally, but since the sparrows associate closely with man, this in a measure relieves them from danger; and, besides this, they have developed a wariness which enables them easily to elude even the cunning cat and other domestic animals. Where it is understood that they are as palatable eating as the reedbird, many of them are annually destroyed, but this is only in isolated localities, and it makes small impression on the great mass. The natural hardiness of the bird, its ability to endure Canadian winters and the heat of the tropics makes it at home everywhere when once established; its natural aggressiveness and marvelous fecundity aids its surprising spread. Where the ground is covered with snow for a long time, and makes it difficult for the sparrow to obtain nourishment, large numbers of them die, but it is from hunger, and not from the severity of the climate. The blizzard of March, 1888, destroyed thousands of them in this neighborhood, and for some time they appeared in diminished numbers. A severe storm in Covington, Kentucky, once choked the sewer's with dead birds, but flocks from the neighboring territory soon rushed in to fill up the gap. We may consider 1870 as the year when the sparrow had become established on this continent, and in five years it had spread over an area of five hundred

square miles in the United States and Canada, and in seven years more it had spread over more than a million square miles, and, no doubt, at the present time it can be found in every state and territory in the Union, while it has increased the extent of its habitat in the states where a few years ago it only existed in isolated colonies.

The structure of the sparrow's bill shows that it is essentially granivorous, and yet at times it destroys many insects. Just how much good is done by the bird in this way can only be found by examining large numbers of their stomachs. Investigation of this sort proves that the sparrow is a miserable failure as an insect destroyer. It never makes a practice of catching insects except to feed its young, and these insects are usually of those species which are most easily secured, and are found where the sparrow most commonly resorts. Only in exceptional cases has it ever made any inroads into the ranks of insect pests. It is even open to question whether it destroyed any of the Eugenia moths in New York, for which it was originally imported. Young sparrows eat many more insects than adult birds, and yet insects are not necessary for their healthful existence, and they can be reared exclusively on a vegetable diet. Out of 522 dissections, including young and old, made by the United States Department of Agriculture, the presence of insects was shown in only ninety-two, or seventeen and six-tenths per cent., of the stomachs examined, while the actual proportion of insect food to other food did not exceed two per cent. Besides this, the greater portion of the insect food taken by these sparrows consisted of species which are either neutral or directly beneficial. A single yellow-billed cuckoo was found to have destroyed 250 fall web-worms besides other insects, and all of them injurious, a bulk equal to the entire amount of insect food in all the 522 sparrows examined. In the city of Albany during 1885 the caterpillars of the white-marked tussock moth were so abundant that they were seen crawling everywhere, even over the boxes that sheltered the sparrows, and yet the birds were never known to disturb the insects. On the contrary, by driving away other birds which naturally destroyed them, the sparrows fostered the increase of the pest. These and other species of injurious insects have thus increased with alarming rapidity in localities where the cause was evidently the protection accorded by the presence of the sparrow.

The sparrow feeds to some extent upon the seeds of weeds, but this benefit is very slight, since the weeds grow where the destruction of their seeds is of little importance. Grain and the seeds of grasses are regularly sought by them, and they do much more injury than is generally imagined. Wheat is their favorite grain, and the damage done to this alone amounts to one-quarter of the whole crop. They usually attack this as soon as the kernels mature, but even when left in shock or stack it is still subject to depredation, for the sparrows devour all the grain in the exposed sheaves. To vary their bill of fare they also attack grapes, cherries, apples, pears and small fruits and vegetables, and the damage done to these crops is always serious. Ornamental vines, evergreen trees and hedges are subject to serious injury when the birds select them for a nesting-place. A sparrow has been known to strip the buds and blossoms from the entire branches of fruit and ornamental trees, nibbling off many times more than it could possibly eat, apparently for amusement, and the dissection of birds shot while thus engaged failed to disclose the presence of any food, excepting the buds and portions of the blossoms. It may be readily seen, therefore, that the damage to fruit trees must be considerable, and much of the injury usually attributed to other causes can probably be traced to this source.

The sparrow is naturally pugnacious and he persecutes many native birds, assailing the chipping sparrow in flocks, and even larger birds when they are rendered by accident defenseless, pursuing them furiously until they are dead. They have been known to attack young robins in their nests, and even domestic pigeons and common fowls are molested for the purpose of robbing them of their food. The scarcity of many of our native birds about our dwellings is to a great extent owing to their quarrelsome dispositions. They seem absolutely fearless and will attack a blue jay or a crow, and by the force of numbers compel even these to retreat. But such birds as associate naturally with man are the greatest sufferers. Among these the blue birds, the purple martin, the robin, the house wren and several swallows are most frequently and seriously disturbed, because their nesting-places are naturally coveted by the sparrow, and many other birds are driven from the vicinity of human dwellings where they naturally congregate.

The sparrow has manifestly few good qualities, and all arguments urged in its defense have been abandoned one by one.

The evidence against its character is conclusive: it is a parasite, and its extermination would be a desirable thing. The difficulties in the way of this, however, seem insurmountable. Bounties offered are practically useless, since so insignificant a number are killed that their loss has no apparent effect on the steady increase. An estimate based on the lowest bounty which would produce any desired result shows that to exterminate the species in Ohio alone would cost the state two and a quarter millions of dollars, and even this would not avail unless the adjoining states pursued a similar course. Since the total extirpation of the pest seems impracticable, this article has been prepared simply to show the true character of the bird and to set forth the necessity of some action looking toward the restriction of its unlimited multiplication on this continent.

Foreign Correspondence.

London Letter.

PHAJUS BERNAYSI.—This is the handsomest of the many forms of Phajus which botanically are only varieties of *P. grandifolius*, but which for horticultural purposes are accorded specific rank. It is flowering now at Kew for the first time, having been received two years ago from Fiji as "a distinct, probably new, *Phajus*, which I found in the woods here, and which has white flowers." In general characters it resembles typical *P. grandifolius*, the pseudo-bulbs being two inches in diameter, the plicated bright green leaves two and a half feet long and four inches wide, the erect scapes three and a half feet high, with sheathing bracts four inches apart and a dozen or more flowers in a compact raceme at the top. Each flower is four inches across, the sepals and petals equal in size, pure white outside, pale sulphur-yellow inside, the folded lip being white, with a faint tinge of yellow inside. The plant grows freely under stove treatment and potted in loose loam. There is a figure in the *Botanical Magazine*, 1873, t. 6032, of a plant imported from Queensland by Messrs. Veitch & Sons, and named in compliment to Mr. Bernays, of the Queensland Acclimatization Society. This plant is darker in color than that now in flower at Kew, and it is said to be a native of Queensland. In their *Orchid Manual*, part vi., page 11, Messrs. Veitch state that the plant flowered by them "is of little value as a horticultural plant on account of the flowers being often self-fertilizing before they expand, and thence lasting but a short time in perfection." All the flowers on the plant now in bloom at Kew are perfect in form, and the oldest flower has been expanded a week, and is still as fresh as the flower which opened to-day. In color it is quite distinct and delicately beautiful in the pale sulphur or primrose-yellow of the inner face of the segments. The type of *P. grandifolius* is not generally popular because its flowers are dull in color, a character which certainly does not belong to *P. Bernaysii*.

ALBERTA MAGNA.—A second plant of this south African Rubiaceous plant is now flowering in a greenhouse at Kew, and from it a picture has been prepared which will shortly be published in the *Botanical Magazine*. When calling attention to it in my letter of a few weeks ago I omitted to mention that, in addition to the brilliant red color of its terminal panicles of flowers, it has a second, and probably more lasting, attraction in its leaf-like calyx-lobes, which are spatulate in form, an inch long and colored bright red. When in flower the calyx-lobes are small and of uniform size, but after the flowers have faded one or two of the four calyx-lobes grow, and apparently assume as bright a color as the flowers. This character is not peculiar to Alberta, but may be seen in the allied genera, *Mussaenda* and *Howardia*. The Alberta is a handsome evergreen shrub. In flower it suggests *Embothrium coccineum*.

CACTUS VS. MAMILLARIA.—If we adopt the western proposal to substitute the name *Cactus* for *Mamillaria*, thereby limiting the use of the term now employed for the whole order to a single genus of that order, we shall, in consequence, be forced to invent a new family name. The term *Cactus*, as now used, has the same general meaning as have those of

Orchid, Fern, Palm, etc. We have Cactus societies, Cactus journals, Cactus shows and Cactus collections. What are they to do for a name? I argue the question solely from the standpoint of convenience, and I claim for the old arrangement the right to stand which long usage and suitability give it. *Mamillaria* is an excellent generic name, as it points out a character peculiar to the genus, namely, the mammae, or nipple-like tubercles which clothe the stem. It is not easy to persuade horticulturists to drop a well-established plant name, but I fancy you might as well ask us to find some other name for the Rose as to ask that we shall call a Cactus something else.

COLONIAL FRUIT.—Our horticultural and agricultural friends at the antipodes promise to supply the English market with fruit in as great abundance, and consequently as cheap, as the beef and mutton which now come from there. Tasmania announces that a shipment of apples for England will be made every week for thirteen weeks, beginning on February 25th, and that the grand total of cases intended for us will be close upon 200,000. We are also informed that a few thousand cases "only" will be shipped from Victoria and other Australian colonies. Three steamers, bringing large cargoes of fruit from the Cape, have lately arrived here, but owing to bad management much of the fruit arrived in an unsatisfactory condition. Grapes, peaches, nectarines, greengages, plums, melons, pears, apples and tomatoes were the principal consignments. I believe the chief cause of failure with such fruit as this is the cold of the "cool chamber." Shippers should try warmer and drier treatment for fruit grown under tropical or subtropical conditions.

W. Watson.

London.

Plant Notes.

The Cherokee Rose.

WE not long ago published a note on this Rose, and, indeed, we have often spoken of its attractive qualities, but it is one of those plants which it is difficult to overpraise. In one of the earlier volumes of *GARDEN AND FOREST* (see vol. i., page 235) there was an illustration of a hedge of this plant in Florida, with some of its long pendulous branches cut away to keep it within reasonable bounds. In the present number (see page 115) we publish an illustration of a flowering branch in which the quality of the individual flowers is brought out more clearly. The practice of spending a part of the winter in the southern states has become so general that most northern people are now familiar with this plant, but those who have never seen it can get a fairly good idea of the character of the flowers from the illustration, when it is remembered that they are considerably reduced, each one being two or three inches across, of a clear white, which appears to the best advantage against the dark evergreen leaves. The plant was naturalized in this country so early that Michaux pronounced it indigenous more than one hundred years ago. But, although we have no record when it was first introduced or how it broke away from the garden and made itself at home in Georgia and spread through the other southern states, botanists usually agree that it is an Asiatic species. It has become so thoroughly naturalized in the land of its adoption, however, that it is seen along the highways, forming high hedges which become at length lofty thickets twenty or thirty feet thick, and absolutely impenetrable. It is as much at home, in fact, as the wild Orange in Florida, or the Barberry on the New England coast. No more beautiful spectacle can be imagined than a long vista bordered with these plants, with their rampant growth and profusion of flowers.

Of course, the Cherokee Rose is tender in the north, and it is such a vigorous grower that it does not give much satisfaction as a pot plant. It is well worth setting out, however, in any large cool greenhouse, where it can be planted in a border in rich well-drained soil, and trained to

the rafters and walls. It needs full sunlight and all the air it can get during the warm weather, and, when once well established, it should be cut back almost as closely as a grape-vine. Hardwood cuttings taken in autumn will make a plant fit to set out in the open border the following June, and, if well grown, it will be large enough to flower the next January. Severe pruning will not be needed the first year, but, afterward, the old wood should be cut out every year in March or April to encourage new shoots, and it should always be well fed when it is growing. In its native state it blooms in April, but by proper pruning the time of flowering can be somewhat regulated, and it can be kept in bloom from January to March. Occasionally flowering branches of the plant are seen in florists' windows, but it would hardly pay here as a commercial plant, since it needs a long time to become established, takes a great deal of room, and then bears but one crop, and not a very long one, every year. It is, however, a most desirable ornament for any large cool house.

The illustration on page 115 is from a photograph by Miss Edith Eliot, of New Bedford, Massachusetts.

ASPARAGUS RETROFRACTUS ARBOREUS.—This plant, introduced to cultivation by Messrs. Lemoine in 1890, seems very distinct from other species of Asparagus. The stems are light colored, as large as a Rye straw, but solid and almost woody, the specimens we have seen under ordinary culture reaching a height of six or seven feet. The chief peculiarity, however, is in their so-called leaves, which are borne on numerous short side stems. These leaves are thin and are arranged in clusters like those of a Pine-tree. Their color is light green. The leaves are attractive and lasting for use in foliage effects with delicate flowers, and will be appreciated as a change even from the beautiful *Asparagus plumosus*. The plant would also be attractive for foliage decorations. Perhaps this species may not be readily increased so as to make it a plant of commercial value, but it will, we think, be appreciated in private greenhouses.

BIGNONIA VENUSTA.—Where one has plenty of head-room in a cool or intermediate house there is nothing better than this good old Brazilian plant for winter blooming. It begins to flower during the dull season, November and December, and continues until the middle or end of March; the warmer the house the earlier the flowers. They are borne in thick clusters in long pendulous racemes, often three feet or more in length, and are of good size and of bright orange-yellow color. Very few greenhouse plants show such immense and showy masses of bloom as this *Bignonia*. Unfortunately, the flowers are not very useful for cutting; they fade quickly unless they can be kept wholly or partially submerged in water; occasionally, however, they can be used with good effect in large decorations where they need last for an hour or two only. It is for greenhouse adornment that this plant is principally useful, where there is a back wall or high gable to be covered, or where a quantity of pendent vines will not interfere too much with the plants growing below. It should be planted in a well-drained border, in rough soil, rotted sods and peat, and care must be taken to keep the roots somewhat confined—that is, too much root-space is undesirable. The strong growth is during the summer months, terminating with the flowers in early winter. After flowering, the plant should rest; the leaves will fade and fall, and water must be given sparingly. The last of May, or in early June, a severe pruning should be given; all the new wood, now fully ripened, should be cut back to two eyes, unless it is desired to extend the amount of space occupied by the plant, when enough for such purpose should be saved. The weak wood should be removed, and any superfluous older stems cut out. Water should now be given, and the vine should be syringed daily. It will break freely and grow rapidly; any weak growths should be pinched out, and the stronger ones carefully trained, but never headed in, for it is on the ends of these shoots that the flowers will come. To check the

mealy bug, which is the only troublesome insect, the old stems need careful cleaning; the foliage should be washed frequently with hose or syringe up to the time of blooming. The propagation is somewhat difficult from cuttings, which should not be made of the very newest growths, but it is comparatively easy by layering in pots, using the new growths in August and September.

OSMANTHUS (OLEA) FRAGRANS.—This is one of the charming old-fashioned greenhouse plants for which the modern commercial florist apparently has little use. It is an evergreen shrub, a native of China, of rather slow growth, but not at all exacting in its requirements. Beginning in early December and continuing through March, it produces abundant clusters of small whitish flowers of most delicious and delicate fragrance, quite unlike the scent of any other flowers, and as difficult to describe as the color of a Saffron Rose. It is said that this flower furnishes the flavor used to scent orange Pekoe tea, a statement that can readily be believed, the fragrance is so oriental. It should

spring planting is often a necessity; the Japan Lilies, for example, have only recently been received.

Japan and China have contributed to our gardens to a surprising degree, and much that has been credited to Japan has probably come from China, but has been received through Japanese channels. But, whatever their original home, we should seriously miss them from our gardens, and our Lily-beds would suffer greatly if deprived of the species from the east. Some of these do not last long with us, as in the case of *Lilium auratum*, which we rarely hear of as thriving for more than a season or two at most. I have certainly never seen it established like the varieties of *L. speciosum*. A Lily more generally seen each year, as its good qualities become known, appears to be a natural hybrid between *L. auratum* and *L. speciosum*, and is known as *L. auratum platyphyllum*, or *L. auratum macranthum*. It would pass for the true *L. auratum* in all respects but for its broad foliage, which is quite as broad as that of *L. speciosum*, and the bulbs live and increase year after year, as do those of *L. speciosum*, in our gardens. This Lily is more expensive than some of the other kinds at first cost, but once purchased it does not need to be replenished, and it blooms regularly every season. Another good

Fig. 18.—A Flowering Branch of the Cherokee Rose.—See page 114.

be grown in a cool house and not overpotted. The drainage should be good, and when repotting is necessary the shift should be a moderate one in March or April. The soil should not be too fine, with some peat and plenty of sharp sand. The propagation is by cuttings of hardened wood in January and February. It is the best plan to keep the leaves entire, removing those only which interfere with the proper placing of the cuttings; neither bottom-heat nor glass coverings should be used.

Cultural Department. Lilies.

THE sooner work is begun in the outdoor garden the better it will be for many plants next summer. Many herbaceous plants begin to make root as soon as frost has left the soil, and this first start should, if possible, be made where the plants are to grow. This is especially true of Lilies, the fall planting of which is always desirable. But as a large proportion of the bulbs cannot be purchased until winter has set in,

hardy Lily is *L. Wallichianum superbum*, one of the most beautiful Lilies known, a native of the Himalayas. It promises to be popular, since it is easily propagated, rivaling the old Tiger Lily in ability to make young bulbs on the flower-stems at the base of each leaf, many of which will flower the second year. It is quite possible that we may yet see it grown in greenhouses as generally as the well-known *L. longiflorum*, which it resembles in some respects. The flowers are tubular, rosy-brown tinted outside, and white, with a rich yellow inside, that has given rise to the name *L. sulphureum*, which is now regarded as the correct name by authorities on Lilies. While this Lily has proved perfectly hardy in Massachusetts without any protection at all, it is better to give it the usual covering of dry leaves in autumn, as is the practice with other kinds.

Other new and beautiful kinds of Lilies of recent introduction are *Lilium Alexandræ*, said also to be of hybrid origin between *L. auratum platyphyllum* and *L. longiflorum*. If it is really a natural hybrid some time must elapse before it can be disseminated in any numbers. The new *L. Henryi*, a native of central China, with the form and rich red spots of *L. speciosum*, is of a uniform rich apricot-yellow in color. At Kew this fine

Lily is said to have proved hardy and strong, making stems over eight feet high, and producing as many as fourteen flowers on a stem. It increases rapidly under the same cultivation given to other kinds, and is, no doubt, a true species, having foliage resembling that of *L. speciosum*. This valuable acquisition suggests that the interior of China holds many beautiful plants desirable for our gardens as yet unknown to cultivation and to science. For *L. Henryi* we are indebted to Dr. Augustine Henry, who found it growing in two places only, near Ichang, on grassy slopes, at 200 to 2,000 feet elevation. The probabilities are that it will prove hardy in this part of the United States.

Among rare Lilies should be named *Lilium speciosum Mel-pomene*, a very richly colored form, perhaps the richest of all the varieties of *L. speciosum*. While it is rare in cultivation, other forms being substituted for it, it should not remain so, for it is not much more expensive than the others, costing about one-third more, and is far more beautiful. An importation of this sort is now daily expected, and we hope to have a fine group of this variety and the best of the white forms, *L. speciosum album praecox*. The latter make a good contrast, and flower about the same time, whether in pots or planted out in the borders.

Lilies which have been protected during winter must not be uncovered too early in April, and a little protection is necessary until all likelihood of frost is past. The young growing shoots are very easily injured by frost, especially if there is no protective growth near them, such as is furnished by a Rhododendron-bed. If the shoots are already above ground when the bed is uncovered they should be covered over with a handful of leaves and left to come through naturally.

South Lancaster, Mass.

Cannas.

THE advance of the Canna to its present position as an ornamental plant is one of the marvels of modern horticulture. Unlike the Star of 1891, which created a sensation when first introduced, Madame Crozy still remains among the indispensable varieties, and a large percentage of recent introductions are seedlings or derivations from this remarkable plant. The yellow border on its petals has given the cue to efforts in the direction of a pure yellow, and this seems to have been the aim of nearly all raisers of new varieties. Improved forms of Madame Crozy have been the result, but the type after all is probably the best. Its moderate height, handsome foliage and short compact spike make it the ideal. Improvements, however, have not been altogether on this type. In crimson we have Charles Henderson and Alphonse Bouvier; the former has the larger spike, finer flowers and dwarfer, sturdier habit. Alphonse Bouvier is an abundant bloomer, but is much taller; these two hold a superior rank in their color. Captain Suzzoni is the best yellow of the sorts that now can be called standard. It is not, however, a pure yellow, though the orange-red spots are so faint that for general effect it may be classed as such. Florence Vaughan is an elegant Canna as far as quality of flower and size of spike are concerned, but it is hardly a yellow variety, and should be classed among the spotted varieties. It has the finest yellow ground with scarlet spots of any Canna yet sent out. Captain Suzzoni as a winter bloomer is superior to Florence Vaughan, and in this respect it is equal to Madame Crozy. Taken from the border last autumn it has bloomed continuously all winter, and is now the brightest and best of any. Florence Vaughan received a check, indicating its relation to the older types, which needed some resting. Paul Marquant is a fine satiny salmon, free, and first-class in every way, especially as a winter bloomer. Paul Bruant is a beautiful orange-scarlet, large in flower and one of the first bloomers. This also has proved an admirable greenhouse variety this winter.

Among dark-leaved varieties, J. D. Cabos, with bronzy leaves and salmon flowers; Egandise, with crimson flowers, and the first bloomer of any, and President Carnot, the handsomest in foliage, make a beautiful trio. J. D. Cabos is hardly comparable with either, the glistening salmon-tinted flower contrasting beautifully with the metallic lustre of the foliage. These are the best varieties now in general cultivation.

In novelties every one is inclined to have favorites of his own. Last summer and autumn I made it a point to note the coming introductions. Eldorado will prove to be one of the finest yellow-flowered sorts this season. It has a large flower, as fine a spike and as good in habit as Madame Crozy, and it is practically yellow. It has some markings, but not enough to detract from the brilliancy or effectiveness of the flower. Every one who sees it is enthusiastic over it. It is very showy and must become popular. F. R. Pierson will probably be the best scarlet of the season. It bears an ideal flower, brilliant

in tone, with only a delicate penciling of pure gold at the centre of the flower, which seems to intensify the scarlet. The petals are very large, round, overlapping each other, reaching near what we must sooner or later obtain in this desirable class of bedding plants—a perfectly round flower. The Belle of Newport is, so far, the only pure yellow Canna. It is very dwarf, and in this respect promises to be of exceptional value as a bedder. It, however, lacks size, but, no doubt, it will be found valuable for hybridizing with the larger-flowered varieties, and may lead toward a new race of dwarf yellow varieties. The flower of the new so-called Butterfly Canna, Golden Wings, may be described as having a deep yellow ground, heavily blotched with brownish crimson. It will be a fitting companion to Queen Charlotte, a novelty of German origin—a scarlet, heavily banded with yellow. Both are beautiful and distinct, and especially adapted for effect when used with the darker-leaved varieties in masses. For bedding purposes, and especially for lines, Oriole will probably surpass any of the banded yellows yet introduced. Columbia is a novelty of American origin, and a very distinct break in character. The heads of bloom are most compact, deep cardinal-red, without any shadings; the spikes branch, and the flowers remain on longer than those of any other variety, a most valuable characteristic. Sunshine is much in the way of Paul Marquant, an unusually free bloomer, and bears the largest flower of any Canna I have seen. It has a soft, satiny lustre, and is not excelled by any of its color. Admiral Avellan I consider an improvement on J. D. Cabos, and this is saying a good deal. It is well worth a trial where a handsome bronzy-leaved variety, which is also a good bloomer, is required. General de Miribel is a good spotted salmon of splendid habit and fine large flowers, and Gladstone is a distinct and pleasing novelty with buff-colored flowers, bordered with yellow. Mrs. Fairman Rogers is a variety in the way of Madame Crozy, which has been honored with a silver medal by the Massachusetts Horticultural Society. The flowers are more heavily banded with yellow than those of Madame Crozy, but its principal value lies in the great size of its branched flower-spike. Its habit is dwarf, and promises to be the best of the Crozy type yet introduced.

Wellesley, Mass.

Cut Flowers for Summer.

IN choosing the location for the cut-flower bed, when beginning garden work in spring, a good water supply should be considered, for during a dry season frequent and thorough waterings will be needed to insure an abundance of flowers. Among the plants readily procurable and particularly useful for this purpose are Bouvardias. Old stumps of these plants which have been in use in the greenhouse during the winter will answer well if cut back closely and allowed to break again before being planted out. The most satisfactory varieties are Davidsoni, The Bride and Elegans; the single varieties, as a rule, are the most floriferous. Stock plants of Heliotrope will also give a regular cut of flowers during the summer, and should be treated in the same way as the Bouvardias.

Carnations are apt to be somewhat scarce in the early summer, unless some of the plants of the former season have been kept over winter in a cold frame. Another plan is to keep the old plants in the greenhouse until outdoor flowers become plentiful. Successive sowings of China Aster should be made in order to prolong the flowering season, for, though these are rather formal flowers, they are useful and add much to the brightness of the garden. Successive plantings of Gladiolus bulbs will also provide good cut-flower material. For this purpose some of the older and less expensive varieties are useful, as, John Bull, Shakespeare, Princess of Wales and Brenchleyensis. Rather deep planting is required for these bulbs. From four to six inches is a good depth, but this may be varied according to the nature of the soil.

The first outdoor sowing of Sweet Peas should be made just as soon as the condition of the ground will permit. In some localities fall sowing is practiced with much success, but, whatever plan is adopted, an abundant water supply is essential to success in our hot summers, and, as is well known, the more the flowers are picked the more freely will they be produced, as the formation of seed-pods checks the growth of Sweet Peas.

Helianthus multiflorus and its double-flowered form are both useful in the herbaceous border and for cutting. Their brilliant flowers are highly decorative when tastefully arranged, and are not so coarse as those of many of the Sunflowers. Roses will naturally suggest themselves to every flower lover, and Marie Guillot, Papa Gontier, Marie Van Houtte, La France and Perle des Jardins are generally satis-

factory as outdoor flowers. A few plants of scented Geraniums should also be included in the cut-flower section of the garden. These will provide a plentiful supply of foliage for mingling with the flowers; for this purpose the varieties having finely cut leaves are most suitable, as most of the scented Geraniums are likely to make a rather coarse growth when planted out in good soil.

Holmesburg, Pa.

W. H. Taplin.

Phajus grandifolius.

THIS evergreen terrestrial Orchid is an old favorite, having been in cultivation for more than a century, and, although one of the first Orchids introduced into cultivation, it is still grown in almost every collection of these plants. The first specimens were brought into England from China, where it is a native, in the year 1778, by Dr. John Tothill. Some time afterward it was found to be a native also of the lower Himalayas, Cochin China and eastern Australia.

The plants now growing here were collected by me three years ago in the mountains of Jamaica, where *Phajus grandifolius* is abundant. Although so plentiful there, I was told that it is not a native of that island, but was introduced about a hundred years ago, and has become thoroughly naturalized. It is found there at elevations ranging from 1,000 to 5,000 feet. I found the largest and strongest plants at an elevation of about 3,500 feet. They grew in rich loam in an open space which looked as if it had been a garden at one time, and they were unprotected from the hot tropical sun. In the same piece of ground *Bletia Shepherdii* grew plentifully.

Phajus grandifolius has ovate pseudo-bulbs, and these when well grown are the size of a large Hyacinth bulb and are sheathed by the imbricating bases of the fallen leaves. The large, dark green leaves are oblong-lanceolate and thirty to forty inches long. Our plants are grown in nine-inch pots, and there are seven or eight flower-spikes to each pot. Many of the spikes are four feet in height and carry twelve to sixteen flowers each. The flowers are four inches across; the sepals and petals oblong-lanceolate, yellowish brown on the inner side and silvery white on the outside. The projecting lip is of a tubular shape, about an inch and a half long, white, with a dark crimson-brown throat. These plants are easy to grow and flower, but if large, well-flowered specimens are desired they require attention and care. The plants should be repotted in spring when they are beginning new growth. They flourish in a compost of fibrous loam, leaf-mold and a small quantity of dried cow-manure. During the growing season they like a warm, moist atmosphere and plenty of water at the roots, and occasionally a little weak liquid-manure. They do well in an intermediate house during the summer, and when the leaves are fully grown they should have cooler treatment and they will then need less water.

Harvard Botanic Garden.

Robert Cameron.

A Few Annuals.—III.

MENTION should be made of the so-called Everlasting Flowers, which are curious and sometimes quite pleasing. Their vogue in cemetery wreaths and bouquets of dyed and bizarre grasses has somewhat abated, and funereal associations have, perhaps, been the occasion of their waning popularity; but a few of them are ornamental in a garden, and they are by no means to be despised when dried and tastefully arranged in vases, especially if fresh flowers are scarce. The prettiest of the Everlastings are the *Acrocliniums* and *Rhodanthes*.

Many climbers are useful in furnishing cut flowers as well as ornamental in the garden, where they can be made to cover bare spaces quickly and effectively. As merely ornamental plants they vary greatly in value, and the annual climbers are not as valuable as the hardy ones, with which a garden can in time be more satisfactorily furnished. Of tender vines, after Sweet Peas, which have already been noted among the best annuals, the Morning-glories, of course, easily lead all others in popularity. *Ipomoea major*, the ordinary form, has seeds which will grow for any one, and which it will in time distribute only too generously. As can be seen in any catalogue, there is a great variety of *Ipomoeas*, many of which are beautiful, and yet have seeds which, fortunately, are not so hardy. The so-called Heavenly Blue, which is the old *Ipomoea rubrocœrulea*, is one of the most desirable. The night-blooming kinds are curious, and may sometimes be seen open on cloudy days. The *I. (Mina) lobata* is scarcely worth growing, since it is uncertain in flowering, and the flowers, when they do appear, are of unsatisfactory color. *Mina sanguinea* is better, having bright scarlet flowers, which are borne very freely, and will be welcomed as a change from Cypress-vines (*Quamoclit*), whose

usual supports of strings and hoops are so prominent in some gardens. Many of the *Ipomoeas* flower shyly, but all are very prolific of foliage. The Allegheny-vine, *Adlumia cirrhosa*, is a native plant of great beauty. It is perfectly hardy, a biennial, which during the first year has a Fern-like effect. The second season it runs freely and produces very pretty small, nearly white, flowers. It is more attractive, however, without the flowers, which soon fade, and give a ragged effect to the plants.

The *Cobæa* usually proves one of the most satisfactory annual vines, as it produces most effective large flowers. The flat seeds are easily ruined in the seed-bed if carelessly watered. However, if planted on edge and carefully tended in a temperate atmosphere, they will germinate safely and grow away rapidly.

Thunbergias are very pretty in gardens, especially when allowed to grow untrained. Their hard seeds germinate slowly, and they require strong heat.

Maurandia Barclayana is the prettiest of the delicate or small-foliaged vines. As it has fair-sized handsome flowers, which it produces very freely on the rapidly growing stems, it may be rated as the best of the smaller annuals.

Climbing *Nasturtiums* cannot be spared from any garden, but these have been listed among the best annuals. *Humulus Japonicus*, Japanese Hops, may more readily be omitted from the garden, unless some wild place is to be covered by a rapidly growing vine which will surely replace itself by seeds, and these it produces in myriads. I do not know of any plant, unless it is the *Centaurea* and *Petunia*, which distributes its seeds so uniformly over a garden, and every one of them seems to germinate. Yet I have known people for whom Japanese Hops would not grow.

If one has available space in the back garden, an assortment of Fancy Gourds will be found very interesting, especially to the younger members of the family. Their quick growth is of daily interest, and the fruits are so pretty or curious or grotesque, as to make the fruiting time one to be pleasantly anticipated.

Elizabeth, N. J.

J. N. Gerard.

Celosias.—These useful plants of the summer months can be grown by any one who will give a reasonable amount of attention to them. *Celosia plumosa* and *C. cristata* are both well worth growing, as they are so useful for cool greenhouse, conservatory or terrace work. In the latter place they will stand a long time, and their showy appearance always attracts attention. Seeds of a good strain are especially needed in growing these plants. Good seeds will germinate in any fairly light soil if placed in a good moist heat. It is best to cover the pan with a piece of glass until the seed is up. As soon as the plants are large enough to be handled they should be pricked off into flats, but kept in a brisk heat, as they should not receive any check after they are once started. As soon as they are large enough they should be potted into four-inch pots, preferably in a rich compost of loam, leaf-mold and cow-manure in equal parts. At the last, six-inch pots should be used for plants of *C. cristata*, and a size larger for *C. plumosa*. I use a little commercial fertilizer, for they are vigorous feeders and must have plenty if they are to form fine heads. They should be kept in a moist heat to protect them against red spider, and the heat of a slow hot-bed is just the place for them, as the glass keeps them dwarf.

Different strains of the *Cristata* type show the combs at different periods, some when in small pots, others after the last potting, and some of the best heads are formed from these. This is a good time to sow seed, and some may be sown later to give a second lot. With a minimum temperature of sixty-five degrees and plenty of moisture and manure strong plants will be assured.

Correspondence.

The Hardiness of the Rose Crimson Rambler.
To the Editor of GARDEN AND FOREST:

Sir,—I have been much interested in what you have said about the Rose Crimson Rambler at various times for several years past, and now that American dealers have plants on sale I should like to inquire whether the experience of the past winter has proved that they are hardy?

Babylon, L. I.

S. A.

[It is too early to answer such a question definitely. Plants may survive one year, even a very severe one, and yet fail at another time under apparently less trying circumstances. We have inquired of several of the firms who

advertise the Crimson Rambler in our columns, and, so far as we have learned, the probabilities are that the plant will prove hardy. Messrs. Ellwanger & Barry write that plants of this Rose which have been out-of-doors all winter with the same protection that is given to other hardy Roses prove to be in first-class condition now, in the middle of March, having borne the winter as well as any others. It is further said that some of the tips of the Crimson Rambler which had not been covered at all have escaped so far without the slightest injury, which indicates that some kind of winter protection is given. Mr. A. Blanc writes that some of their plants of the Crimson Rambler have been left out at West Grove, Pennsylvania, all winter, and have so far withstood the severe weather without any apparent injury. Mr. Patrick O'Mara, of Peter Henderson & Co., reports that they left out four plants of this Rose, one on each of the four sides of a house in Hackensack, New Jersey, so that the plant could be tried in every exposure. Both the wood and the buds of these plants are still plump and perfectly sound.

It is to be hoped that these prophecies of hardiness may prove true, because large plants of this Rose when in bloom, as we have seen it in England, are objects of striking beauty. Even if it should not prove quite hardy, it would be very valuable for conservatory decoration.—ED.]

Some New Hybrid Roses.

To the Editor of GARDEN AND FOREST :

Sir,—A few days since I received a box of charming roses from Jackson Dawson, of the Arnold Arboretum. As these were new hybrids and most promising, a few notes of them ought to interest those who appreciate the value of Roses which are useful for other purposes than the mere furnishing of cut flowers. These Roses are all from stock of *Rosa multiflora*, or rather they are seedlings of the delightful Dawson Rose, a cross between *R. multiflora* and General Jacqueminot, fertilized by pollen of Madame Gabriel Luizet and General Jacqueminot.

Of the flowers sent me, I was especially attracted by one which was a most exquisite little one, no larger than *Rosa multiflora*, but double, very fragrant, and a clear, light rosy pink color. Its pollen parent is Madame Gabriel Luizet, and it seems of the same habit and free-flowering character as *R. multiflora*. I can imagine no more beautiful floral sight than a trellis covered with a plant of this in bloom. There were others, double and semi-double, ranging from the color of Apple blossoms, through various shades of rose to a clear dark cerise. In size they vary from the small flowers noted above to some two inches in diameter. Judging from the flower-sprays, there appears to be the same variation in their habits as there is in the quality of their perfume.

These Roses received a silver medal last June from the Massachusetts Horticultural Society, and they are sure to be valued by those who have been awakened by the beauty of the more simple flowers of the species which are now finding favor in the best gardens.

Elizabeth, N. J.

J. N. Gerard.

Market Flowers in Private Gardens.

To the Editor of GARDEN AND FOREST :

Sir,—I am much interested in your reports of the Carnation exhibition in Boston. That a society should be devoted to the development of a single flower; that meetings should be held to discuss the merits of its different varieties, to compare the results of different methods of propagating and cultivating it, and to listen to learned dissertations on its fungous enemies by scientific experts; and that exhibitions consisting of these flowers almost exclusively should attract crowds of visitors—all these are novelties in the history of American floriculture, and they certainly promise to instruct the public on every essential point which the growers of Carnations need to know. We sometimes hear certain flowers sneered at as fashionable, but a flower is not likely to gain such a position unless it has genuine merit. Certainly the Carnation excels in many ways. It has bright color, attractive form and exquisite fragrance. It has foliage, too, which heightens the effectiveness of the flower, and I confess to some feeling of surprise that in the reports of all your correspondents I saw not a word about the foliage as a part of the beauty of the plant. A flower with a

stem as stiff as a lead-pencil and two inches across was sure to get commendation, while everybody knows that a Carnation flower is never so beautiful as it is when seen in connection with its own leaves, and the leaves of some varieties are much more effective as a foil and setting to the flower than others.

Perhaps the reason of this is that Carnations sell without regard to their foliage, and it is not surprising that commercial growers should devote themselves to supplying what people are willing to pay for. They do business with the same motive which impels other business men, and it is right that profit in business should be their original aim. We often hear flowers grown by florists spoken of contemptuously as something inferior to those grown in private places, but it is very plain that a different purpose ought to rule in a commercial establishment and a private establishment. All the efforts that florists are making to produce flowers of the greatest substance and lasting power and availability for their particular use is commendable. If it will pay them to grow nothing but Carnations, and even only one variety of Carnation, this is the one thing they ought to do. But is this quite the best way to manage a private collection?

This is just the point to which my long preamble is tending. While it is undoubtedly the proper course for a commercial grower to grow the few things that will sell, one would think that a man with a private collection would derive greater satisfaction from growing a variety of plants. Certainly he will not get the greatest enjoyment out of his garden if he devotes it mainly to flowers which can be bought in the nearest florist's shop. There are scores of plants which have a beauty so delicate that it makes them unprofitable to sell either as plants in flower or as cut flowers, and one cannot help but feel that the place to find such things is a private collection. One can go to a commercial establishment and thoroughly enjoy half a dozen houses full of Carnations and admire the skill with which they are cared for. In the same way, long houses filled with Roses for market are interesting to every flower-lover, but why a man with a range of greenhouses for his own enjoyment should have in them little else than flowers which can be bought on a street-stand is surprising.

While the quality of florists' flowers is growing better year by year, it has sometimes seemed to me that the quality of the collections in private glass houses and private grounds is deteriorating in variety and growing less and less interesting. Of course, it is hard to prove such a statement, and the natural reply to it is, that, as we grow old, memory throws a rosy halo over the past and glorifies all we saw in youth, while if we could see the real thing now it would look much less attractive than the imaginary one does in our musing moods. But I think I can remember fine old places along the Hudson and in the suburbs of Philadelphia and Boston where there were once collections of beautiful hardwood plants, and the same houses now are filled with soft stuff to furnish cut flowers. In fact, there are many choice old plants which I hardly know where to look for in these days. Once we used to see plants which were not rare or hard to secure, but which were grown into such magnificent specimens that they compelled admiration simply for their size and luxuriant vigor. We now see fine Palms and Cycads, Dracænas, and the like, and often they are crowded together in such a way that the individuality of every plant is lost, and the house looks like a tropical jungle. But there is a generation of Americans growing up who have never seen a well-grown Fuchsia, for example. What I am trying to say in a roundabout way is that whether it be the fault of owners of plant collections, or of their gardeners, these private places are wasting their opportunities in trying to compete with florists in growing florists' flowers, and that where these great private gardens are devoted to anything besides the furnishing of cut flowers, they do not so much seek to attain what is beautiful as that which is odd and expensive.

R. A. Weyman.

Syracuse, N. Y.

Jasminum nudiflorum.

To the Editor of GARDEN AND FOREST :

Sir,—From this latitude southward, where *Jasminum nudiflorum* will survive our winters in the open air, it almost always shows some flowers with the warm days of early March. So far, however, not a bud has expanded. We have potted plants in cold storehouses which are now beautifully in flower. We often use this plant as a climber among other vines in pots, and we invariably get a fine display from it in February and March. It might be used in this way to advantage much oftener than it is now.

Recent Publications.

The Silva of North America: A Description of Trees which Grow Naturally in North America, exclusive of Mexico. By Charles Sprague Sargent, Director of the Arnold Arboretum, Harvard University. Illustrated with figures and analyses drawn from nature by Charles Edward Faxon. Volume VII. Lauraceæ-Juglandaceæ. Houghton, Mifflin & Co., Boston and New York. 1895.

The purpose of this work and the way in which it is being carried out are both so well understood, that it is only needed here to glance at the contents of this volume to show that our rich forest flora continues to sustain the interest in the subject which was aroused by the appearance of the first volume. In addition to the great Laurel Bay of California, Umbellaria, the Perseas of our southern Atlantic and Gulf coasts, and several other species of comparatively limited range, such well-known trees as Sassafras, four species of Elm, two of Hackberry, two of Mulberry, three Sycamores, four Walnuts and eight Hickories are described in this volume. Of the fifty-four plates, from drawings by Mr. Faxon, it only needs to be said that they continue to show that accuracy and refinement which place them in the very front rank of work in their class.

The Florida Sketch-book. By Bradford Torrey. Houghton, Mifflin & Co., Boston and New York.

This is a reprint of a series of papers written for the *Atlantic Monthly*. Their aim is simply to embody Mr. Torrey's recollections of a pleasant vacation tour, part of which was spent in the wilds of eastern and southern Florida, part in the hilly region in the northern part of the same state. The writer visited Florida for the purpose of studying the birds of this semi-tropical region, and of contrasting their habits with those of the same and kindred species in their New England home. The subjects are such as would suggest themselves to a naturalist while exploring new fields, but the treatment is individual, and the whole book has a delightful atmosphere and reflects throughout the charm of a happy personality.

It is refreshing, in these days, when there seems no end to the making of Nature books, to come upon some unpretending little volume like *The Florida Sketch-book*, which displays on every page the clear vision of the true observer. For Mr. Torrey's touch, though light and often playful, as should be the touch of one who writes in holiday mood, is always firm and true and sometimes exquisitely tender. Underlying the bright fancy and gay humor, which are characteristic of his attitude toward Nature, is a solid base of accurate knowledge, combined with a delicate appreciation of every phase of natural beauty. He has, moreover, something of the poet's gift—that perceptive sympathy with the life of Nature, which is as incapable of analysis as the color of the rose or the perfume of the violet, and which separates by a narrow though impassable gulf the record of the true interpreter from that of the mere "suburban reporter." This gift manifests itself with as much certainty in some apparently careless allusion to the habit of a flower or the ways of a bird, as in the formal word-painting of a landscape. And, although Mr. Torrey may not have realized Thoreau's ideal description of a flower, so that he can reveal what the child sees in it to admire and love, he often, by a delicate imaginative touch, establishes at once some subtle sympathy between the reader and the inhabitants of the woods or fields. Thus, when he speaks of the Mullein stalk as "presenting arms along the roadside," the soldierly bearing of the plant is given at a single stroke, and when he characterizes the Partridge-berry as a "Yankee in Florida," we feel the breath of northern woods in the monotony of the Pine-barren.

In Mr. Torrey's interpretation of bird-life we find the same full sympathy. Sometimes it is revealed in an elaborate study of an individual, as in his description of the omnipresent great blue heron, familiarly known as "The Major," which is always at home near the water, and there

is water everywhere in Florida. "On the beach, as everywhere else, the heron is a model of patience. To the best of my recollection I never saw him catch a fish there; and I really came to think it pathetic, the persistency with which he would stand, with the water half-way to his knees, leaning forward to the breakers, as if he felt that the great generous ocean, which had so many fish to spare, could not fail to send him at last the morsel for which he was waiting." No reader can forget the happy phrases in which the tree-top flirtations of the flickers are described; we fairly tire of the monotonous music of the tufted titmouse, which pipes on and on without rest or variation, "as if his diapason stop had been pulled out and stuck fast"; and we at once appreciate the preternatural gravity of the pelicans when we are told that the writer could never see even a single pair of them going by in Indian file "without feeling as if he had been to church."

Though the object of Mr. Torrey's tour in Florida is to study the manners and customs of his feathered friends in their southern environment, no sooner does he enter the land, where it is always afternoon, than, in spite of his Puritan inheritance, he yields to that delightful southern insouciance "which takes life as made for something better than worry and something pleasanter than hard work." And he confesses with charming frankness that the pleasantest of all his Florida memories are of the occasions when, forgetting all his botany and ornithology, "he climbed the hill in the cool of the day, and after an hour or two spent on the plateau strolled back again, facing the sunset through a vista of moss-covered Live Oaks and Sweet Gums." One hardly knows where to stop when beginning to quote, and we might continue for pages to show how all the air which rests upon this half-tropical scene is filled with leisure and languor; but Mr. Torrey cannot divest himself even in this golden land of the influence of his New England inheritance and discipline. The quiet and incurious hours, which are so delightful to recall, owe their very fullness of enjoyment to the acute powers of observation which have been trained to act with automatic precision by many a vigorous tramp, with open eyes and alert senses, over New England hills. It is his deep love for his northern home and his familiarity with every phase of its varied beauty which enable him to interpret with so much poetic feeling the vague and evasive charm of the southern landscape. "A Yankee in Florida" might well serve as a subtitle to his little book, for he never forgets New England's woods and hills. Sometimes in a felicitous phrase he contrasts the characteristic features of the northern and southern landscape, as when he remarks that the "pine wood-sparrow does for the southern Pine-barrens what the field-sparrow does for the northern berry pasture." Sometimes the contrast is instructive, as when writing of the unconfined beauty of the road borders, he says: "The southern highway surveyor, if such a personage exists, is evidently not consumed by that distressing puritanical passion for 'slicking up things,' which too often makes his northern brother something scarcely better than a public nuisance. At the south you will not find a woman cultivating a few exotics beside her front door, while her husband is mowing and burning the far more attractive wild garden that nature has planted just outside the fence." Or, perhaps, the reminiscence is full of tenderness, as when in the course of his journeys he comes upon a solitary hermit-thrush in the thicket, as he occasionally did, and not one of them ever sang a note. "Probably," he adds, "they did not know that there was a Yankee in Florida, who, in some moods, at least, would have given more for a dozen bars of hermit-thrush music than for a day and a night of the mocking-bird's medley." The book is delightfully free from any effort to point a moral, but it again demonstrates that the more one loves his home and the more intelligent is the delight he takes in its natural beauties, the more profound is his sympathy with the novel phases of nature in remote and strangely different regions.

Notes.

Mr. Hamilton Gibson has been invited to give his illustrated lecture on the Fertilization of Flowers before the next annual meeting of the American Florists at Pittsburg.

Mr. J. H. Hale writes to the *Florists' Exchange* that he could find in his orchards last year, where no special cultivation had been used, smooth and fair specimens of the Crosby Peach eleven and a half inches in circumference.

The frontispiece of the *Popular Science Monthly* for March shows a fine portrait of Thomas Nuttall, the famous explorer and botanist, whose *Genera of North American Plants*, published in 1818, moved Dr. Torrey to declare that "it had contributed more than any other work to the advance of the accurate knowledge of the plants of this country." The portrait is accompanied by an attractive sketch of Nuttall's diversified, adventurous and prolific life and of his singular personality.

Antirrhinums are useful border flowers, usually hardy here, and white sorts are especially desirable. At the last meeting of the New York Florists' Club, Mr. W. R. Wood, of West Newton, Massachusetts, exhibited a vase of large pure white flowers, which were said to be a variety of *A. majus*. The long stems, well furnished with unusually large flowers of perfect purity of color, were most attractive. If this variety flowers as freely as ordinary Snapdragons it ought to be a desirable addition to greenhouse collections.

During the past winter California escaped those periods of cold weather which were so disastrous to fruit-growers in many parts of the world, but at the close of last week there was heavy frost in the Sacramento and San Joaquin valleys, which did great damage to the apricot, almond, cherry, peach and prune crops, as the trees were still in blossom or the fruit had just set. As the Sierra Nevada and Coast Range were both covered with snow, it was feared that the frosts might continue for several nights.

Mr. Jackson Dawson, of the Arnold Arboretum, has raised a hybrid with *Rosa Wichuraiana* as the seed parent and *Rosa rugosa* as the pollen parent. The plant has the perfectly prostrate habit of *R. Wichuraiana*, lying flat to the ground, but with the vigorous constitution of *R. rugosa*, and large, deep green glossy leaves. The flowers are single, nearly as large as those of *R. rugosa* and of a clear rose-pink color. If it had no flowers whatever the lustrous leaves and vigorous habit of the plant would make it desirable.

Occasionally vessels from the south of Europe bring over small numbers of what are called nut-cones. They are really the cones of *Pinus pinea*, in shape and general color resembling somewhat a small pineapple. When brought into some warm place, as, for example, near a steam radiator, the scales quickly begin to reflex, commencing at the base, and turning back release the piñons or edible seeds. The motion of the scales as they open is so rapid as to be plainly visible, and is quite interesting to people who have never seen the spectacle, and this exhibition gives a value to the cone apart from the nuts which it contains.

Dr. Peters, of the Botanic Garden of Gottingen, has been experimenting with seeds taken from different depths of soil in a dense wood from 100 to 150 years old, which had been arable land for many years before it became woodland. His object was to discover how long the seeds of weeds would retain the power of germinating after they had been buried in the soil to a depth where they could not sprout. Soil samples were taken at various distances from the surface to the depth of a foot. These samples were placed under genial conditions, and the seeds which germinated were raised and cultivated to a flowering stage. Although the land had ceased to be arable between 300 and 400 years before, the weeds of cultivation were abundantly represented, and Dr. Peters claims to have proved that the seeds of many field and pasture plants retain their vitality considerably more than half a century.

A summer school of forestry, continuing from the 8th of July until the 10th of August, is to be held under the auspices of the American Association for the Advancement of Education, at Avalon, New Jersey, fifteen miles north of Cape May, on the coast. A large part of this island is covered by forests of Oak, Cedar, Pine and Holly, and there are remarkable dunes which show the effect of drifting sand. The director of the school will be Mr. John Gifford. Dr. Charles Dolley is the lecturer on Zoölogy in relation to Forestry; Dr. T. N. Lightfoot lectures on Geology in relation to Forestry; Dr. S. Egbert lectures on Forestry in relation to Health; Albert B. Entwistle lectures

tures on the Uses of Woods. Students to the school of forestry, for which a fee of \$10.00 will be charged, are admitted to the courses of the Assembly in Natural Science free.

From the twenty-sixth annual report of the Park Commissioners of West Chicago, it seems that the parks in that city are suffering from the same abuses of which the Park Board of Buffalo complain. It is said that visitors make walks across the turf and mutilate the plants. There is no cure for such a state of things except a more elevated and refined public sentiment. A community which allows the beauty of its public grounds to be trampled out so far proves itself lacking in certain elements of civilization. The people who are helping to devastate the Chicago parks, the wealthy men in this city who have tried more than once to turn Central Park into a trotting-course, the wheelmen and horsemen who are endeavoring now to confiscate a part of the Buffalo park system for bicycle tracks and speedroads, all belong to the same class. They are not intentionally public enemies. The trouble is they are not yet completely civilized.

Mr. G. F. Scott Eliot, who left England in September, 1893, on a botanical exploration of Mount Ruenzori and the country north of Albert Edward Nyanza, has just returned, and at the last meeting of the Linnæan Society gave an interesting account of his journey. The country north-east of Victoria Nyanza is described as a rolling plain, fertile and grassy, 6,000 feet above the sea, while Mount Ruenzori, where he spent four months, reaches an altitude of 18,000 feet. The sides of the mountain are clothed at the base with a thick growth of trees resembling the Laurel of the Canary Islands, above which are Bamboos to the level of 10,000 feet, and above that again a substance which the explorer could only liken to a Scotch peat moss into which he would sink at every step for a foot or more. Among the plants he saw were a gigantic Lobelia five or six feet high, Hypericums resembling those found in the Canaries, Violets and Cardamines. Large trunks, like those of *Erica arborea* of the Canary Islands, but indicating trees eighty feet high, were also seen. In addition to a large collection of dried plants, Mr. Scott Eliot brought home and presented to Kew a collection of living plants, including various bulbs and Orchids.

The main dependence for potatoes this year is the domestic crop, which is in striking contrast with the condition of the supply of this staple a year ago. Since October 1st 730,000 barrels of home-grown potatoes have been handled by New York wholesale dealers, 230,000 barrels more than were received here in the same period a year ago. In the same months during the present season only 60,000 sacks of European potatoes came into this port, whereas above 338,000 sacks from Great Britain and the Continent passed in during this period last season. Nova Scotia, Prince Edward Island, Cuba and Bermuda are also minor sources of supply. Potatoes from Bermuda cost fifty cents a half-peck; parsley from the same islands brings seven cents, and beets twelve cents a bunch, while heads of Romaine lettuce cost twelve cents each. Cuba still sends egg-plants, okra, peppers and onions. String-beans from the southern part of Florida are a scarce luxury, and cost the unusual price of a dollar a quart. Small lots of tender and crisp lettuce from Florida find ready sale at good prices, and the first cabbage from that state has been quickly bought up by dealers in choice vegetables at \$4.00 a barrel, as high a wholesale price for this quantity as is asked for one hundred heads of northern-grown winter cabbage. Danish cabbage has advanced to \$10.00 and \$12.00 for a hundred of the firm, large, white heads. Tomatoes from Key West and Havana come in varying grades; those of ordinary quality may be had as low as fifteen cents a quart, the better-colored and more delicate ones costing thirty cents a pound, while choice hot-house tomatoes of uniform size and rich color command eighty cents a pound. The first Charleston asparagus costs \$2.50 a bunch. Kale, chicory, spinach and escarole, from Norfolk, are moderately abundant. The only green peas now offered here are the few coming from California, and these cost seventy-five cents a half-peck. The last California cauliflowers sell for fifteen to thirty-five cents a head, and the smaller and whiter hot-house cauliflowers bring thirty-five cents each. Hot-house radishes cost five cents a bunch, and tender young carrots the same price. Rhubarb, from Long Island, is ten cents a bunch, mushrooms seventy-five cents a pound, and Boston cucumbers twenty cents each. Among winter vegetables Brussels sprouts cost twenty-five cents a quart. Half-a-dozen roots of long, well-blanced Rochester celery cost fifty cents; the smaller celery from New Jersey commands half that price. Choice Vineland sweet-potatoes cost fifty cents a half-peck.

The Winter Aspect of Trees.

IN the eyes of those who have genuine love for them, trees do not lose their beauty when their leaves fall; and, indeed, for such persons they have an especial attractiveness in the dreariest season of the year. We often hear the coniferous trees, which hold their foliage all the year through, praised for their value in a winter landscape, but deciduous trees, whether taken singly or in groups, have also their uses in the scenery of this season when they reveal beauties which are at other times unseen. There are no richer colors in a winter landscape than the warm browns of a distant wood, and there is nothing for delicacy of tint to match the faint mist of color that hovers above a thicket, a sort of a haze—it may be of violet or rose, or soft gray—composed of the mingled colors of the various twigs in the shrubbery. But, aside from the beauty in color and form of trees in mass, individual deciduous trees never display in perfection the dignity and grace of their framework until after their covering of leaves has fallen, and they then reveal to the careful observer the reason for many of their most striking peculiarities when in full leaf. For example, the attitude and gesture of different trees are quite distinct when under the stress of a high wind. This depends upon the way in which the branches bend and recover in the gale. In the winter one can readily see how the long slender branches of a Sugar Maple, most of which stand out at equal angles from the central stem, will sway in a different way from the sturdy and horizontal limbs of an Oak. We can see, too, how a tree with large and widely separated limbs, like some of the Oaks and Chestnuts, will have the grandeur which comes from an alternation of deep shadows and strong lights, while another tree, like an Ash or a Maple, before it acquires a strongly individual expression with age, will have a smoother and more sunny surface, in which the idea of gracefulness predominates over that of sturdy strength.

Of course, there are details of the color and texture of the bark of individual trees and the arrangements of their spray which can best be studied in winter. The Beech is one of our native trees whose winter aspect is particularly pleasing. Gilpin, in his classical work on *Forest Scenery*, is inclined to deprecate the picturesque value of the Beech;

he pronounces its skeleton deficient in strength and firmness, the branches at the best being disproportioned, awkward and fantastically wreathed, while the bushy spray gives it a disheveled look. He admires, however, the trunks of old specimens when "they are studded with bold knobs and projections, and have sometimes a sort of irregular fluting, which is very characteristic." There are no American Beeches which have been so long pollarded as the famous Burnham trees, which are so impressive for the size of their hollowed trunks, even after the maltreatment which they have suffered. But we are inclined to think that the American Beech is a more impressive tree than the European, although the latter is strikingly beautiful, especially in youth. An old American Beech-tree certainly has dignity of form, and the bark is even more beautiful than that of the European Beech. It has a smoothness of texture unexcelled by the bark of any other tree, and a blue-gray color which looks still more clean when contrasted with the red-brown and abundant spray. Thoreau notices two of the most beautiful characteristics of our Beech when he says "no tree has so fair a bole or so handsome an instep as the Beech"; for the sturdy way in which the great roots curve out to grip the soil is noticeable in every well-grown tree. In a note in one of his journals in early winter, Thoreau also speaks of the thick, inviting bed which the fallen leaves of the Beech make on the ground: "Beautiful, perfect leaves, unspotted, not eaten by insects, of a handsome clear leather color, like a book bound in calf, crisp, elastic, covering the ground so cleanly as to tempt one to recline on it and admire the beauty of the smooth boles from that position, covered with lichens of various colors. The trees impress you as full of health and vigor as if the bark could hardly contain the spirit, so that it lies in folds about their ankles like the wrinkles of fat in infancy."

The illustration on page 125 gives an excellent idea of the proportions of a Beech-tree which has reached mature age, and of the peculiarities of its ramifications, although it is at too great a distance from the observer to show the quality of its bark. This particular specimen has a trunk girth of nine feet and a half six feet from the ground, and its branches cover a circle sixty-five feet across. It stands in South Hingham, Massachusetts, and we are indebted to the kindness of Mr. F. W. Brewer for the photograph from which our illustration is made.

The Work of Women in Village Improvement.

AMERICAN villages are not always desirable places of residence. With proper attention many of them could probably be made more healthful, and certainly more beautiful—or less repulsive—and they could be so organized as to offer their inhabitants greater social and educational advantages. That the well-being of all who live in country villages could be promoted if more thought and labor were given to their sanitary condition and general appearance is an evident truth, and it was to better these fundamental conditions of life that village improvement societies were originally founded, although from the very outset the originators of the movement conceived the still broader purpose of stimulating the love of nature and the development of artistic feeling.

Now, it is true that many of these associations have not fulfilled the sanguine hopes of their originators. Many of the promoters of the movement enlisted in it with no definite idea of what was to be done, no realization of what was important and essential in the project, no adequate knowledge, no artistic feeling, no genuine love of nature. Sometimes there was a lack of earnestness and enthusiasm, and this meant a lack of money to carry on the work. Sometimes there was zeal without knowledge, and this meant too many trees planted, or trees planted in the wrong place, and the invariably fatal results where work which can only be done by an expert is entrusted to a journeyman. And yet the majority of these societies have justi-

fied the wisdom of their founders, and there are many villages in the country which owe to them a good water-supply and sewage system, a general air of thrift and neatness, with improved roads and sidewalks, shade-trees, sprinkled streets, tree-embowered public squares and school-grounds. In many of these villages the railroad station and its well-planted surroundings prove a most favorable introduction to the stranger, who will see nothing to offend the eye in the way of rubbish heaps, tumble-down fences or obnoxious advertisements.

The movement is not dead or dying, and it is worth the attention of any one who lives in a small town, and therefore all such persons will do well to read Mr. B. G. Northrop's article in the March number of *The Forum*, entitled "The Work of Village-Improvement Societies." Here they will find illustrative instances of what can be done, and of what has been done by the movement inaugurated forty years ago with the incorporation of the Laurel Hill Association of Stockbridge, Massachusetts. The account of what has been achieved by this association is most instructive, and no one will doubt the statement that every acre of land and every homestead in Stockbridge has appreciated in value by reason of this society. There are rapid sketches of many other societies in the western as well as in the eastern states where the great benefit of concerted effort is shown, not merely in the way of accomplishing certain ends which are impracticable by individual effort, but also of exciting public sentiment so that it reacts upon individuals and prompts them, not only to improve their own property, but to bestow valuable gifts upon their fellow-townsmen.

The effectiveness of these societies in securing public libraries and the value of similar associations in cities like Springfield, Massachusetts, and New Haven are also recorded, but, perhaps, the most interesting fact which Mr. Northrop brings out is the dominating part which women may play in these local, and yet public, enterprises. The Laurel Hill Association was originated by a woman, and the members of the Honesdale Improvement Association, which is called the model society of Pennsylvania, are all women, although men are admitted to honorary membership, and a Young People's Auxiliary Association, including school-children, has been enlisted to protect flower-beds and shrubbery and gather waste paper scraps into neatly painted and labeled boxes. That women do not concern themselves exclusively with the ornamental branches of village improvement is shown by the fact that in Honesdale the first things advocated were improved sewerage and sanitation; and a similar spirit has marked the work of the Woman's Town Improvement Association of Montclair, New Jersey. A recent report of the Honesdale Association, as quoted by Mr. Northrop, says: "We did not overestimate the public spirit of our townspeople and their hearty coöperation in our endeavors. This is notably the attitude of our Town Council in every appeal we have made to them." And it is added that the citizens and the local papers, irrespective of political parties, heartily support this active body, composed of influential women of tact and zeal, who, at the birth of the association, were two hundred and fifty in number.

These assertions have a peculiar interest as indicating why, in this, as in many other branches of public service, women may do better work than men. Being less absorbed by business cares, and personally free from public responsibilities of a general sort, they have more time and more zeal to bestow upon local public matters than men, while, as a rule, their tact is finer. But the main point is that, being "out of politics," they are more readily credited than men with unselfishness and a pure concern for the public welfare. The history of the Woman's Club of Chicago and of other similar bodies in other large cities has proved this fact, and it demonstrates that men and newspapers of all shades of opinion will support a movement inaugurated by women, when, had it been inaugurated by men of different political opinions, they would

have felt moved to oppose it. What is true in large cities is as true of small towns; and we believe that if the women of America will generally devote themselves to such useful and fruitful public work as has been accomplished by their sisters in Honesdale and Montclair, they will find that they are not without influence, even though they cannot vote.

Trees of Minor Importance for Western Planting.

THE principal deciduous trees that succeed in the west are Cottonwood, Box Elder, Russian Mulberry, Silver Maple, Catalpa, Black Locust, Honey Locust, White Elm, Green Ash, Black Walnut, Wild Cherry and Burr Oak. Besides these, White and Red Oak and Chestnut grow well in certain localities, principally toward the eastern part of the region south of the Dakotas. In addition to these, several other well-known species can be successfully grown in the Plain region. The Hackberry, or Nettle-tree, has a natural distribution almost as wide as that of the Box Elder, being found throughout Nebraska and South Dakota, and along the streams of northern Kansas. It grows rapidly under cultivation, and succeeds very well on high land. It endures shade well, at least while young, and can be used for mixing with Box Elder and other shade-enduring species.

Ailanthus was recommended almost without qualification in the early days of Kansas tree-planting, but the past few dry seasons have proved that it is worthless on high land, and of little value in any locality. Grown as coppice—that is, to be cut to the ground every few years—it makes a great deal of fuel, but in close plantation it can hardly be grown as a timber-tree. The species is too tender for northern Nebraska and the Dakotas.

A few Kentucky Coffee-trees at Hutchinson, Kansas, are doing well, and as this species is native throughout eastern Kansas, there should be no difficulty in its cultivation, except in high localities. Its large decompound leaves make it an interesting tree for lawn planting.

Very fine specimens of Sycamore were also seen at Hutchinson, but this tree is not successful on high ground and cannot stand northern winters. Strong two-year-old trees were killed to the ground at Brookings, South Dakota, after making a good summer growth.

The Russian Poplars and Willows have been quite extensively planted in South Dakota, but it is doubtful if they are acquisitions of special value. Mr. James Smith planted them extensively at Cresbard, Faulk County, South Dakota, in 1883 and 1884, and for several years they were very promising, but the attacks of the Cottonwood-leaf beetle, *Lina scripta*, followed by the excessive drought of the past few years, have completely destroyed his plantation. *Populus Certinensis* was largely planted at Brookings, where it failed when grown side by side with Cottonwood, a good proportion of which survived. *Salix fragilis*, a Russian Willow, has produced a great mass of branches, and cannot be grown in tree form, though introduced as a forest-tree.

The Laurel-leaved Willow, where protected from the beetle, is a beautiful small-sized tree that can be grown throughout the west.

The Basswood, or Linn, is native along all the streams in the eastern part of the plains, and would, doubtless, be successful under cultivation in places not too dry. There are few farm uses to which the wood can be put, however, so that its principal value in western planting would be to add variety to lawn or grove. Few of our native trees have such large clean leaves, and the sweet fragrance of its flowers, combined with its luxuriant foliage and clean growth, should make it an acceptable lawn-tree. The Hawthorns grow well in eastern Nebraska and Kansas, but these can hardly have a place in artificial planting, as every purpose they could fill would be much better served by the Plums.

The Plum is one of the native trees of the west, and every farmer should plant plum-pits in the margin of his

shelter-belt, not only for the excellent fruit which he is likely to get if he plants selected seed, but because the Plum, being a low bushy grower, brings the branches of his plantation down to the surface of the ground, and is, therefore, effective in keeping out winter winds. The Nebraska Choke Cherry, *Prunus Besseyii*, and even the Sand Cherry, can be grown in the same way, and the Sand Cherry, besides bringing the fine branches close to the soil, affords an abundant supply of food for birds. The tree is hardier than the Russian Mulberry, and it can, therefore, supplant that variety in the north.

London Letter.

DENDROBİUM JOHNSONAE.—Messrs. F. Sander & Co. advertise this week an auction sale of "nearly a thousand plants, in superb condition," of this large-flowered species, which has been known since 1882, when it was introduced by Messrs. J. Veitch & Sons, for whom it was named *Dendrobium Macfarlanei* by Professor Reichenbach. Four years later (1886) the professor described it as having "flowers quite excellent; they surpass those of *D. Phalaenopsis*, and are as large as those of *D. formosum*." In 1891 Mr. Rolfe, on receiving "a fine raceme of this splendid species for determination from Admiral Fairfax, who collected the plant in New Guinea," renamed it *D. niveum*, as the name *D. Macfarlanei* had been given to another very different plant from that named for Veitch by Reichenbach. But even this second name was not allowed to go unchallenged, Sir F. von Mueller, the well-known Melbourne botanist, pointing out, in *The Gardeners' Chronicle*, in May, 1891, that the correct name for the plant introduced by Veitch was *D. Johnsonae*, and that he had described it in May, 1882, in the *Southern Science Record*, and that it had been discovered in New Guinea by the missionary, the Rev. James Chalmers, whose particular wish it was that his magnificent Orchid should bear the name of a Miss Johnson, of Sydney, who has interested herself in the New Guinea mission.

Reichenbach wrote in 1886 that "this Dendrobie, in its chaste and glowing beauty, may one day be an object of the most ardent interest to those who cultivate Dendrobiums."

According to Messrs. Sander & Co.'s description, this *Dendrobium* is a free grower with pseudo-bulbs and habit resembling those of *D. densiflorum*. As many as thirty spikes have been borne by a single imported plant; there are fifteen or more flowers on each spike, each flower being four to five inches in diameter, snow-white, suggesting a white *Laelia anceps*. The mid-lobe of the lip is variable in color, usually blue, sometimes orange. It is figured in *Reichenbachia*, t. 61, where the flowers are described as "pure white, with the exception of some slight purple stains on the side lobes of the lip." Mr. Rolfe informs me that he has seen flowers which were totally white. Messrs. Sander & Co. say *D. Johnsonae* should be grown with its north Australian congeners (*D. Phalaenopsis*, *D. bigibbum*, etc.), and that when making new pseudo-bulbs a high temperature is necessary. There are from three to eight flowers on the spikes represented in the figure in *Reichenbachia*.

DENDROBİUM SPECIOSISSIMUM.—This is a new species which Messrs. H. Low & Co., Clapton, have introduced, and now advertise for auction sale as a fine *Dendrobium* discovered by Sir Hugh Low on Mount Kina Balu, in Borneo, in 1867. He sent dried specimens of it to Kew in 1867, but they were too imperfect to be named with certainty. He describes it as being similar to *D. formosum*, but the pseudo-bulbs are much hairier, and the flowers, which are of great size and substance, are white, with a blotch of rich purple-red at the base of the labellum. The flowers are borne in clusters of about four on the ends of the short pseudo-bulbs. Sir Hugh Low says he found it growing on a Mag-

nolia. *D. Lowii*, to which this new species is evidently allied, was found in the same country by Sir Hugh Low. In that species, however, the flowers are buff-yellow, with an orange-red blotch on the labellum. All the *Dendrobies* of this section, *Formosae*, are large and handsome in flower, and have hairy pseudo-bulbs.

NEW CATASETUMS.—The two last issued parts of *Lindenia* (January and February, 1895) are devoted to eight pictures of Monsieur Linden's new Catasetums, some of which he exhibited in a collection at a meeting of the Royal Horticultural Society, and which were then voted one of the most interesting and attractive exhibits seen in London in recent years. Monsieur Linden says he has twenty distinct species or varieties or natural hybrids, whichever one prefers to call them. Some only differ from *C. Bunge-rothii*, as figured in the *Botanical Magazine*, in color, but others are quite different in form from that species, and are more like *C. macrocarpum*. Both these last-named species are found growing together in a wild state, and the inference is that they have been naturally hybridized, these beautiful and wonderful plants in the possession of Monsieur Linden being the result. I do not remember anything more remarkable in the whole history of Orchid collecting than the discovery of this collection of Catasetums by Monsieur Linden's collector. The conditions under which they were found have yet to be made known. Nor is there a parallel among the many hybrid Orchids raised artificially, true hybrids, as a rule, showing comparatively little variation. Catasetums have not yet been artificially hybridized; possibly they refused to ripen seeds under cultivation, still the experiment might be made with *C. Bunge-rothii* and *C. macrocarpum*.

The genus had not a prominent position among popular Orchids until *Catasetum Bunge-rothii* was introduced, and even that fine species was not strong enough to lift Catasetums into the front rank. But these new ones, figured by Monsieur Linden, and most of which I have seen in flower, are really grand Orchids. I know no tropical Orchid more worthy of a place in the garden than the Catasetums which Monsieur Linden calls *C. imperiale*, *C. splendens*, var. *atropurpureum*, *C. Lindeni*, *C. mirabile*, and, in fact, all that I have seen of this set. Their origin will be as interesting to botanists as their large, richly colored, singularly formed flowers will be to cultivators.

ELOPHIELLA ELIZABETHÆ.—Two plants of this handsome Orchid are now flowering at Kew. They were obtained in the autumn of 1893, when they were newly imported from Madagascar, and they have been growing ever since in teak baskets suspended over a hot-water tank in a tropical house; they are planted in pure sphagnum moss, and they have been liberally watered always. The strongest has made leaves three feet long by one and a half inches broad, four to each growth, and one bears three, the other two spikes. These are horizontal, a foot to eighteen inches in length, straight, dull brown-purple, with ovate-concave bracts. There are sixteen flowers and buds on the strongest spike and these are like the figure in the *Botanical Magazine*, t. 7387, in size, form and color, except that they are not tinged with rose on the inside of the segments. The growths are not as yet nearly as strong as the imported bulbs show they ought to be, and I am doubtful of our being able to keep this Orchid for any length of time. Plants of it are also in flower in the St. Albans nurseries.

CATLEYA PERCIVALIANA is a beautiful and useful Orchid which deserves to be more largely grown than it is. Several plants of it here are in flower now, the flowers of medium size, elegant in form, and of the richest shades of maroon-purple and mauve. It was introduced in 1882 from south-west Venezuela, where it is said to "invariably grow on rocks, not on trees, and in full exposure to the sun, generally in the vicinity of river courses, which, in the rainy season, afford abundant moisture to the plant." Under cultivation it thrives when planted in peat and sphagnum, either in a basket or on a raft. The preference for rocks is a peculiarity of another handsome winter-flowering Orchid,

namely, *Epidendrum bicornutum*, which forms thick masses on exposed rocks near the sea in the island of Trinidad. It also thrives in peat and sphagnum in baskets, requiring excessive heat and moisture while making new growth.

MAXILLARIA LINDENIÆ.—The March number of *Lindenia* contains a figure and description of this handsome Orchid, which was introduced from Peru in 1893 by *L'Horticulture Internationale*, and flowered in their nursery in the following January. It was first described by Cognieux in the *Journal des Orchidées* last year, p. 362. I lately saw a flower of what is evidently the same plant and which is in the collection of Sir Trevor Lawrence, under another probably erroneous name. It is a near ally of *M. venusta*, but the segments are broader, the figure in *Lindenia* suggesting a flower of *Lycaste Skinneri*. They are white, with longitudinal lines of purple on the sepals and the outside basal portion of the lip, the front lobe inside being yellow, with red marginal blotches. The differences between it and *M. venusta* are pointed out in *Lindenia*, the principal one being the monophyllous pseudo-bulbs and the shorter, broader flower segments in *M. Lindeniae*. It is likely to thrive in the cool Orchid-house.

THOMAS BAINES.—This famous English gardener succumbed this week to an attack of influenza. He was seventy-two years of age, having been born in North Lancashire, at Claughton Hall, where his father was gardener and his grandfather before him. Thirty years ago Mr. Baines was without a rival as a cultivator of specimen pot plants, and his collections were rarely second to any wherever he exhibited them. Hard-wooded greenhouse plants grew to an enormous size and flowered with wonderful prodigality under his treatment. He was equally successful with Palms, Ferns, Pitcher-plants, Crotons and Orchids, the specimens of these shown by him in London, Manchester, all over England, in fact, being marvels of cultural skill, even to men who were skillful cultivators themselves. For the last twenty years Mr. Baines practiced with conspicuous success as a landscape-gardener. He was an ardent disciple of the natural style and used to speak of *Coniferae* as the bane of many English gardens. I have always known him as "Old Tom." He was a prolific writer for the gardening press, and he wrote an excellent book on the cultivation of stove and greenhouse plants.

W. Watson.

London.

Plant Notes.

PITTOSPORUM UNDULATUM.—This plant is an evergreen greenhouse shrub, introduced into British gardens from Australia toward the end of the last century. It is one of the best of the genus, the long, linear, wavy leaves giving a graceful appearance to the otherwise somewhat stiff habits of growth; the leaves are also a rich deep green, shining, and of good substance. It thrives in a cool house in winter, and in summer can be used for decorating the piazza or grounds. The small white flowers open in January and continue into March; they are borne in clusters on the tips of the branches, have a pleasant fragrance and continue in good condition for weeks. This is a good house plant; the combination of flowers and foliage is effective, and it will withstand the usually trying conditions of living-rooms if kept well watered. The cultural requirements are simple; a rich soil, with plenty of peat and sharp sand, is the best potting material, and overpotting should be avoided. The propagation is by seeds, which are abundantly produced on older plants; the seedling grows quickly, making blooming plants in from two to three years. It is well to keep up a fresh supply of young specimens, as the older plants frequently lose much of their symmetry and become too large and overgrown for handling with ease. It thrives out-of-doors in Florida, and is one of the common shrubs of southern California.

PELARGONIUM HENRY COX.—This is the prettiest of the so-called golden tricolor section, and has been valued in green-

houses for some years for its beautiful foliage. None of the *Pelargoniums* are as bright-colored as this little plant, whose vigor is apparently expended chiefly in the production of highly colored leaves, which, when well grown, are more showy than many flowers. They have usually a bright green centre, a zone of brilliant red, with black markings and a broad edging of clear light yellow. White stems are also a distinct attraction of this plant. It needs a rather subdued light in a warm house, but cannot be coaxed into rampant growth. Owing to its slow increase it is not a favorite with dealers, and is seldom offered by plantsmen, so that it is probably not widely cultivated. The flowers are borne infrequently and are of little beauty, being small and of a light magenta color.

GALANTHUS ELWESII.—This fine Snowdrop is now produced in large quantities by European growers, and consequently is offered at such low prices that it is almost as cheap as the common *Galanthus nivalis*. It is sometimes called the Giant Snowdrop, an excellent name, for it is our old friend magnified, and that, too, without added coarseness or any objectionable quality. It is as early to bloom, as hardy, and has the form and peculiarity of blossom and coloring which we associate with the first flower which ushers in our spring. It is a native of Asia Minor, and, although known as early as 1854, was not introduced into gardens by the man whose name it bears until 1875. It can hardly be called common even now, since it is only recently that bulbs have been grown or collected in sufficient quantities to supply the demand. This, like most other Snowdrops, gives the best results after it has been planted several years; it must be well established, growing compactly in clumps, to give an abundance of flowers. It is not necessary to separate them every three or four years, as is the case with so many bulbous plants. One of the best positions for these, or other early spring-flowering bulbs, is along the foundation-wall of the house or greenhouse; they can be planted directly against the brick or stone work, and so obtain not only good protection, but also additional warmth; unlike other plants, they do not suffer here from the summer drought, because their growth comes in late autumn or early spring, when there is plenty of moisture. This Snowdrop makes a good edging, and can be naturalized in grass or on the borders of a shrubbery.

ERANTHIS HYEMALIS.—This plant, commonly known as the Winter Aconite, is one of our earliest flowers. It is in bloom now, with Snowdrops and Crocuses, showing its bright yellow flowers, which are of good size and are supplied with more foliage, in the form of a deeply cut involucrum, than we usually find in plants at this season. It is a native of western Europe, and has been long in cultivation. It belongs to the Buttercup family and has a tuberous root, a corm; it is usually classed and cultivated with the "Dutch bulbs." The tubers should be planted as early in autumn as possible; they are quite small, and not infrequently arrive in poor condition, suffering from too long exposure to the air. It is a good plan to plant them in sand—that is, after preparing the soil and removing a sufficient quantity of earth for the purpose, put half an inch of sand over the surface thus exposed, then plant the bulbs and cover them with an equal amount of sand, after which the soil removed can be replaced and the planting completed. The tubers are thus surrounded with sand and are less likely to be injured by too much moisture. This *Eranthis* should be grown in a warm, sheltered, sunny position; it may also be used in the wild garden, and in grass, provided the latter is not too thick and well kept. In favorable situations it sometimes propagates itself abundantly by seeds.

CLIVIA (IMANTOPHYLLUM) MINIATA.—This is one of the old-fashioned greenhouse plants which is thoroughly good and admirably suited for private places. If kept in a cool house, it is now in good bloom, showing its large highly colored orange-red flowers in full clusters on stout stems, well relieved by the thick mass of dark glossy green foliage. Although introduced forty years ago, this Ama-

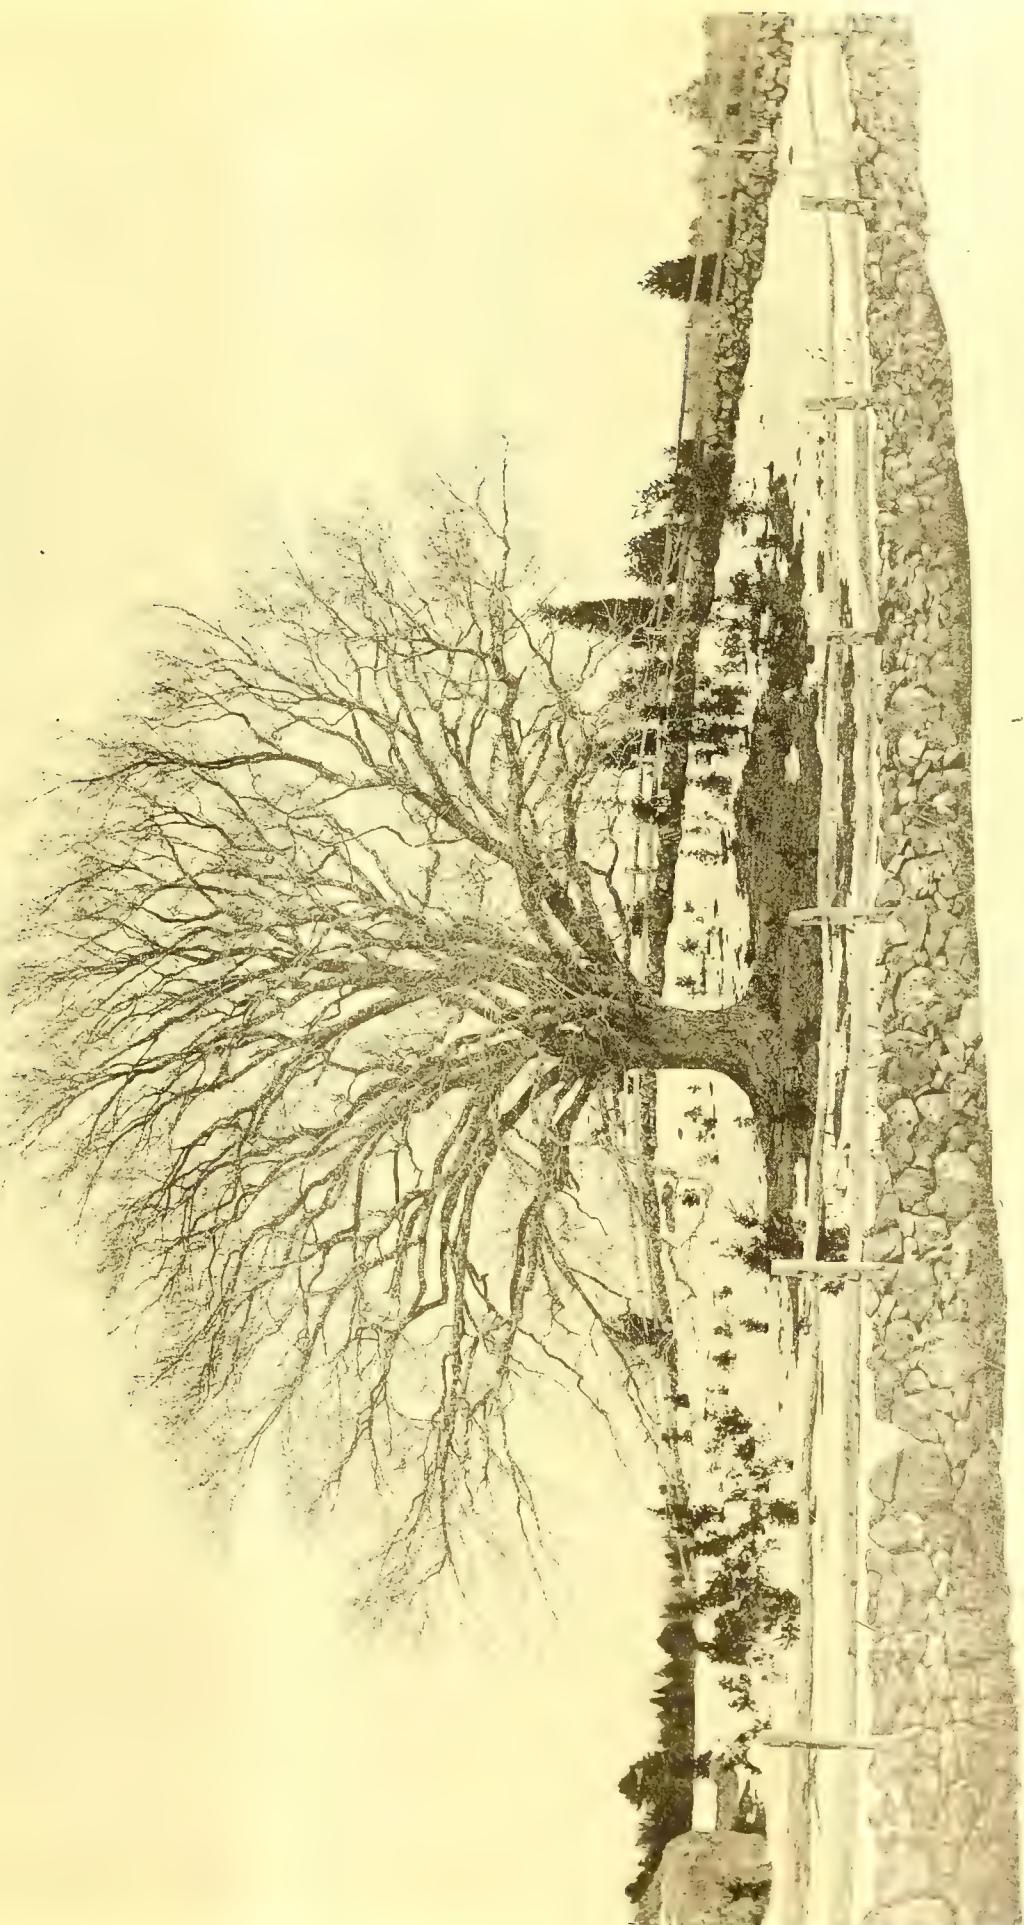

Fig. 19.—Beech Tree in South Hingham, Massachusetts.—See page 124.

rylid is still one of the best of winter-flowering plants. Clivias thrive in a warm rich soil made of rotted sod and peat, and, since they are kept for several years in the same pot or tub after they have attained size, it is well to add coarsely broken bone and charcoal when potting good specimens. The propagation is sometimes by seeds, but more commonly by division, either by removing some of the offsets or by tearing an old plant to pieces. This last is best done just after the plant blooms; the small plants thus obtained should be planted in five or six inch pots in a rather sandy soil; if well done they will often produce flowering plants in one season. Seeds are not easily obtainable; it is said that the production of seeds weakens the old plant, and they are seldom used except for procuring new varieties. In summer good-sized plants are useful for decorating grounds and piazzas. Too much praise can hardly be given to the splendid race of hybrids and seedlings which have been raised from this plant in Belgium and England.

Cultural Department.

Vegetables for Private Gardens.

TWENTY, or even ten years ago, it was a comparatively simple task to select a list of vegetables for home use, but with the annual introduction of the numerous varieties found in the catalogues of seedsmen, the problem has become complicated. It is a popular error that a majority of these novelties are old favorites with new titles. It is only fair to say in defense of the seed dealer that this is not so, for while some novelties are fictitious, most of them are genuine, and they indicate a marked advance on the types of a few years ago. The fact is, that there is a large increase of critical growers who demand improvements to suit their special wants, and the seed dealer who fails to meet this demand is left behind in the race.

I am closely in contact with competent gardeners, both commercial and private, and know that the varieties used by the former class are not of great use to the others, as a rule, and my object in these notes is to point out what qualities are desirable in vegetables raised for the home table. The notes will also show that one who plants for his own table should avoid many sorts used by the market-gardener, whose object is to grow a radish that "bunches well," or a pea that "fills the basket" quickly, or a muskmelon that is "grand for shipping," features absolutely essential for commerce, but often secured only at the sacrifice of the highest table qualities. The best way to accomplish this purpose will be to give a list of vegetables with the qualities most to be desired in each, and to add in each instance the names of such as approach most nearly the ideal standard.

BEET.—Freedom from fibrous or woody texture, constancy of color, a smooth clean root, smallness of foliage, are qualities to be most desired.

Dewings Blood Red, Eclipse, Edmand's Red Turnip, Long Smooth.

BUSH BEANS (wax and green podded).—The best varieties make strong, compact plants, free from runners, bearing shapely pods that are slow to develop stringy or parchment-like character, both elements of toughness. Round podded varieties are generally best and most tender.

Early Red Valentine, Extra Early Refugee, Refugee (or 1,000 to 1), Black Wax, Wardwell's Kidney Wax.

POLE BEANS.—Secure all points, as in Bush Beans, but see that a sort is chosen that "takes poles" freely.

Horticultural Pole, Old Homestead, Golden Cluster Wax, Golden Champion Wax.

The best Pole Lima Bean is certainly Dreer's Improved.

CABBAGE.—Compact habit, small leaf-veins, short strong stem, few outside leaves; if for keeping, solidity of head; if for early use, tenderness and delicate flavor in green state are essentials.

Jersey Wakefield (early), Early Dwarf York, Succession (medium early), Late Flat Dutch.

CAULIFLOWER.—Self-protecting foliage—that is, the habit of the leaves to fold inwardly, which insures a tender white flower; smooth surface of flower; freedom from green leaves growing through the flower. Compact habit of plant and ability to withstand extreme climatic conditions are points to secure.

Extra Early Dwarf Erfurt, Thorburn's Gilt-edge, Henderson's Early Snowball.

CARROT.—Depth and character of soil is essential to success-

ful cultivation of long varieties. If the soil is unfavorable, the roots will be forked and generally irregular. Bright color and absence of core are essential; a small compact top is also an advantage where room is valuable.

French Forcing and Early Scarlet Horn for soups; Early Half-long Carentan, the best of all; Half-long Danvers.

CELERY.—Flavor and freedom from string in leaf-stalks must have first consideration, and sorts deficient in these qualities should be left alone. The red varieties are the best, though generally considered less ornamental. A test of crispness and solidity is to snap the stalks; the more strings shown the tougher it will be.

White Plume, Pink Plume, Golden Dwarf, Perle le Grand, New Rose.

SUGAR CORN.—Sweetness is to be desired first and always. Small cob, deep grain, low-earing habit, ability to resist smut (early red-cob varieties are most subject to this), strong husk, which generally keeps the grain tender a long time, are all desirable qualities.

Perry's Hybrid, Stabler's Early, Hickox, Country Gentleman (the best), Stowell's Evergreen.

CUCUMBER.—Secure strong vine, freedom in setting fruit, medium size, symmetry of shape, firm flesh, few seeds and delicate flavor.

Early White Spine, Cool and Crisp, Livingston's Evergreen.

LETTUCE.—Varieties with large veins in the leaves are to be avoided; compact, close-heading habit is essential; never plant a sort with a heavy stem growing where the heart should be; thin, tender leaves, as distinguished from "flannelly" leaves, should be sought. The foregoing points will always secure good color and tenderness. Ability to resist "running to seed" is a hard point to cover; some seasons will encourage this fault in the best varieties. For sweetness of flavor none can surpass the Cos or Romaine sorts.

Curled Simpson and Black-seeded Simpson are early and loose-headed. Boston Market and Golden Queen are early and solid-headed. Salamander and Henderson's Big Boston are solid-headed summer sorts.

MUSKMELON.—Flavor must be supreme here. A good variety should have thin rind, and the seed cavity should be small. These points will insure depth of flesh, which should also be fine-grained and entirely melting. Color in the flesh is not of importance generally, though the very best varieties happen to be red or salmon fleshed.

Netted Gem (green-fleshed), Jenny Lind (green-fleshed), Emerald Gem (salmon-fleshed), Christiana (salmon-fleshed).

WATERMELON.—Desirable points are the same as in the Muskmelon generally, but a large "heart" is essential, this being the best-flavored part of the fruit.

Cole's Early, Ice Cream (white-seeded), Florida Favorite, Dark Icing.

ONION.—Good-keeping qualities, symmetrical shape, freedom from neck, and mild flavor are the prime requisites.

White Portugal, Yellow Globe Danvers, Southport Red Globe, Southport White Globe, Southport Yellow Globe, Prizetaker.

PUMPKIN.—The two sorts named below are both fine-grained and deep-fleshed. The first is a smaller and more finely bred selection of the latter.

Calhoun, Cheese.

PEAS.—Here, if anywhere, every one knows what he wants. I merely submit a list of sorts arranged in their order of maturing, adding the height in feet attained generally by each sort.

Henderson's First of all (two and a half feet), American Wonder (one foot), Chelsea (one and a quarter feet), Advance (two feet), Everbearing (two and a half feet), Heroine (three feet), Admiral (four feet), Champion of England (five feet), Telephone (six feet).

RADISH.—A small top and fine tap-root; the top should occupy but a small portion of the surface of the bulb; the latter should be clear in color and free from rootlets; the flesh should be crisp and mild in flavor; above all, it must grow quickly, otherwise it will be pithy. I have purposely included only the small delicately flavored sorts.

Red Forcing, Scarlet Turnip, French Breakfast, Long Brightest Scarlet.

SQUASH.—For early summer use grow either White Bush, scalloped, or Bush Summer, crook neck. The latter is the drier-fleshed sort. For keeping, select sorts with hard, but thin, shell, small seed cavity (insuring deep flesh) and fine-grained flesh of rich dry flavor.

Early Prolific Marrow, Boston Marrow, Essex Hybrid (the best-flavored).

TOMATO.—Do not grow the biggest varieties. Secure a strong, but not rank, grower with medium-sized fruits that are

produced freely. The flesh must be solid, the core perfectly tender, seeds few, and there must be no seed cavity or tough skin. The shape should be round, without depression at the stem or blossom-end, and there should be no corrugation.

Ignotum (the best of all), Dwarf Champion, Favorite, Beauty, Trophy, Perfection.

TURNIP.—Small top and root, good-shaped bulb, rapidity of growth, tender flesh and mild flavor.

Early Snowball, Red-top Strap-leaf, Purple-top White Globe, Golden Ball or Orange Jelly.

Bloomfield, N. J.

S. A.

Flower Garden Notes.

ALTERATIONS are needed in the garden that have suggested themselves during the past season, and if, as often happens, there was not time to make these in the early fall, they should be started as soon as the soil is in workable condition. The roots of plants and trees seem to begin their work before the frost is really out of the ground, and certainly the earlier plants are moved the more likely are they to make a good display.

Paeonies should be moved very early, especially if the roots are to be divided. They are generally considered difficult to transplant, but this is not true if they are moved early enough and all the tubers taken up without damage, a sharp knife being used to sever the parts near the buds, so that they may not be injured. If these details are seen to, the plants will flower as well during the succeeding summer as though they had not been disturbed. The Tree Paeonies are not seen in gardens as often as they deserve. They are perfectly hardy with us; they flower as freely as the herbaceous kinds, and much earlier in the season before the arrival of the rose-bugs; this is a great advantage, for it is difficult to think of the later kinds without associating them with this troublesome pest. The old *Paeonia officinalis* is also early-flowering, and belongs to a different section, being, indeed, a true species, with several varieties. The old original scarlet is a fine showy plant in the border, coming in soon after *P. tenuifolia*. *P. corallina* is a single-flowered early species with coral-red flowers. This plant is rare in gardens, and is a native of Asia Minor. Another good garden-plant is *P. Wittmanniana*, from the Caucasus, with very distinct foliage, and single creamy white flowers early in the season. *P. corallina* and *P. Wittmanniana* are proving quite hardy here, and add much to the interest of the garden early in the season, between the flowering of spring bulbs and the majority of true herbaceous plants. Single-flowered Paeonies are not often seen, partly on account of their rarity in trade-lists, but their beauty is undisputed. *P. albiflora* is more common, but is grown by few cultivators, though it is a fine companion for the above-named sorts, and is the parent of the race of our numerous garden varieties. It is not commonly known that in California, and I think also in Oregon, a Paeony is found growing wild. This Paeony, *P. Brownii*, is not a showy plant, and for this reason is but little known, but it is a true Paeony, indigenous to the United States.

It is now proven that the Eremuri can be grown here as easily as in Europe, and they are among the most noble of hardy plants. We have three specimens established here, but have thus far flowered only *Eremurus robustus*; the others will probably flower during the coming season. The long, thick, fleshy roots of the Eremuruses are peculiar in their construction; they radiate from a central crown-bud and spread in all directions, making it difficult to pack them safely. Our roots came from Holland in good condition, and *E. robustus* flowered the first summer after planting, as noted in GARDEN AND FOREST last year. The other two kinds are *E. Himalayicus* and *E. Olgæ*. We planted them in a situation that insured dryness in the fall, so that the crowns should ripen after flowering. A thin covering of manure was spread over the soil in fall as a mulch rather than as a protection. Eremurus-seeds seem to be somewhat erratic in their germination. We sowed all that matured as soon as they were ripe, and only two plants have come up, while Mr. Endicott stated in GARDEN AND FOREST some time since that seeds he sowed came up thickly under the same treatment. Eremuri should be planted in the fall, as the foliage dies down soon after the plants flower in summer, and reappears very early in spring; it would, therefore, be unwise to disturb the roots in the spring unless this cannot be avoided.

The stock of hardy Pyrethrums is easily increased at this time, or as soon as the young shoots appear above ground. These may be taken off as low down as possible and the cuttings put in sand. They will root quickly and flower during the coming summer as well as if they were left on the old roots. Old clumps may also be divided, and then there are

always some shoots that may be spared for use as cuttings. For the best double kinds it is desirable to have a few reserve plants, since the old clumps sometimes die out if left too long in one place and the soil becomes exhausted. Propagation cannot be done too soon after the shoots show above ground in spring. Old plants of the Oriental Poppies must also be moved at the first peeping of the shoots, as these are early-flowering and strong-growing plants. They need rich soil and fall planting, if this is possible. To propagate more Poppies, as soon as the roots can be lifted they should be cut in pieces an inch or two long and these should be placed in sand in a warm house when they will sprout in a week or two. They will make fine stock to flower next year if these young plants are set out in May in good soil. Root-cuttings are the only reliable means to reproduce any special variety, as from seed scarcely any two will be alike.

South Lancaster, Mass.

E. O. Orpet.

Hints on Potting Orchids.

FOR potting material many good growers now use peat alone, while others believe in a mixture of peat and sphagnum, which has the advantage of retaining the moisture better. As the sphagnum gets worn out sooner than peat, more frequent shifting is needed, but, where this can conveniently be done, the mixture is, no doubt, better than peat alone. In either case the material should be broken up and well washed to remove all eggs of snails and insects, then left to dry again before using. Baskets are preferable to pots for most of the more commonly grown species, such as Cattleyas, Dendrobiums, Lælias, and, in short, all that require a plentiful supply of air at the roots. For others, such as Cypripediums and Odontoglossums, which require the roots kept rather cool, pots or pans are the more suitable. In shifting, shake the plants well out, and if they have suffered in any way from stagnation the roots will need to be well washed, all decayed root and parts should be cut away, and particular attention should be paid to removing all dead matter from around the eyes, so as to have them perfectly clear. Thorough drainage should always be given, and the addition of a few pieces of charcoal above the crocks is very advantageous. In placing the plants in the baskets or pots, see that they are set so that the roots from the young growth to be made this year will have plenty of room to enter the compost. If the plants are placed in the centre without regard paid to this point when the young growths have pushed their roots, they will not be found in the basket or pot, but to be over the side of it.

Where the plants have few or no roots it is a good plan to tie a little peat or sphagnum around the base with a strip of raffia; this keeps them in shape and protects them when being placed in position, and since firm potting is essential it makes sure that the material is packed closely around them.

Tarrytown, N. Y.

William Scott.

Chrysanthemums.

THE arrival of new Chrysanthemums marks the beginning of the busy season for the cultivator of these flowers. The old varieties on hand, intended for specimen plants, will be considerably in advance of these new sorts. Although we try all new introductions which show any promise as specimen plants, we do not rely on them, but rather on tested kinds. Exhibitors, however, all things being equal, usually get most credit for well-grown plants of striking novelties, especially in the matter of color. Portia won a good deal of credit last season as an exquisite pink of two shades. Iora, also, had many admirers; the delicate mauve flowers are composed of curled petals, beautifully arranged. Clinton Chafant was another novelty of exceptional value. Unfortunately, very little can be gleaned from the catalogues concerning the value of novelties as bush specimens. They are seldom tested as such, and, if at all, in a very unsatisfactory way. One dealer wrote me that varieties as specimen plants were profitless to handle, so generally has the rating been confined to the blooms as the final test.

The tips should be taken from newly arrived plants, and, as stated in a previous note, these often make the best plants, and certainly the best specimen flowers. The plants should be placed in the garden in May and treated in every way as pot-grown plants are treated, giving them the benefit of careful stopping, tying and watering during dry weather. If they develop the foundation for good specimens by the middle of August we lift them. We consider August the best time for this work, and have never had the loss of foliage so much complained of when the plants are lifted later.

We make only three stages in the potting of our plants.

Growers differ, and, no doubt, it would be safer for the inexperienced to make four. Knowing the character of most of the varieties we grow, helps us to decide on this plan. We shift them from two to four inch pots, and from six to twelve inch pots. The nine or ten inch stage might be added, and for many growers this will be the most convenient limit. Specimens from four to five feet in diameter may be grown in a ten-inch pot. Again, it might not be advisable to shift a poor plant into a twelve-inch pot, and judgment must be used. We are not afraid to make this shift in any case. We use a rather light loam, not very rich, relying on the judicious use of stimulants later on. We do not use any sand, although this is needed in heavy soils, but we add some leaf-soil. We pack loosely, and find this provision against overwatering a safe one, and overwatering is a common misfortune in the cultivation of Chrysanthemums in the earlier stages. If care in watering can be counted upon it is as well to use twelve-inch pots, but not otherwise. At no season is it more important to attend carefully to the stopping of plants, for now, perhaps, more than later, foundation is made for future development. A poorly shaped plant now is not likely to make a good specimen later on. The tips should be taken when an inch or two long, and the softer the better.

Stock plants for cuttings intended for specimen blooms, stored in cold frames, will be moving now, and if they have made five or six inches of growth, as is likely if they have been unusually protected, it is better to cut them over. Nothing will be lost thereby, as there will probably be an abundant crop of cuttings by the first of May. Those stored in the cool greenhouse have already been cut over and are now breaking from the bases. These we shall top-dress in a few days and place in cold frames. In the mean time we shall take every leaf-eye and shoot we can get of reputable novelties.

Bordeaux Mixture and Color Tests.

To the Editor of GARDEN AND FOREST:

Sir,—The use of color tests to determine the presence of copper in solution offers a very convenient method for preparing the Bordeaux mixture. The necessity of weighing and straining the lime required by the formula each time the mixture is prepared is thus obviated. This method simplifies the preparation of the mixture so much that those who have learned to use it will not like to give it up unless it can be shown that it is unreliable, or unless something better is brought forward to take its place. So far as our present knowledge goes, no more convenient method than the color test has yet been suggested, neither have the color tests been shown to be unreliable when rightly used.

The work of fighting fungous diseases of cultivated crops for the season of 1895 will soon be upon us, and as some articles published in the columns of GARDEN AND FOREST and elsewhere within the last few months have tended to cast doubts on the advisability of employing one of these color tests, the potassium ferrocyanide, it may be well to consider briefly some of the objections to its use.

In an article on pages 456 and 457 of the last volume of GARDEN AND FOREST Professor Lodeman calls attention to the unusual russetting of apples and pears noticed in many western New York orchards in 1894, and especially to "the important point that Bordeaux mixture, however prepared, increased the evil," and expressed the opinion that the most severe cases were found in orchards sprayed with Bordeaux mixture made by following the potassium ferrocyanide test.

On page 497 of GARDEN AND FOREST, 1894, Professor Jones states that after thorough trials he has no hesitation in sanctioning the use of the ferrocyanide test in preparing Bordeaux mixture for spraying Potatoes, yet in his work in 1894 a russeted appearance of apples and pears followed the use of Bordeaux mixture made by this test for spraying orchards.

Trees at the Geneva Station sprayed with London purple or Paris green with the addition of lime only, so that the arsenites might not spot the foliage, also showed a russeted appearance of the fruit and spotting of the foliage. Trees sprayed with Bordeaux mixture to which no arsenites had been added showed russeted fruit as a result of the spray, as also did trees sprayed with Bordeaux mixture combined with London purple or Paris green. In all three instances corresponding unsprayed trees were practically free from this peculiar russeted fruit. The only substances used in all three instances were the lime and water, in one case combined with an arsenite, in one case with copper sulphate, and in one case with both copper sul-

phate and an arsenite. The Bordeaux mixture was prepared by means of the ferrocyanide test. Taking into consideration only the evidence given here, one might conclude that it was the lime and water in the spraying mixtures that caused the injury rather than the use of the ferrocyanide test.

Bordeaux mixture made according to the ferrocyanide test was used at the Geneva Station in 1893, prepared according to the same formula that was used in 1894. No injurious effects were seen either on foliage or fruit sprayed with this preparation in 1893, even when six treatments were used, but the same preparation sprayed but once in 1894 showed some injury both to foliage and fruit. The prominent new condition which attended the work in 1894 was the unusual cool, cloudy and wet weather during a considerable portion of the spraying season. At Geneva during the week from May 17th to May 23d, 1894, there was less than three per cent. of the possible amount of sunshine, and during the two following weeks but fourteen per cent. and thirty-nine plus per cent. respectively, showing an exceptionally long period of cloudy weather for this locality. The records also show that during this period the temperature was low. From May 16th to June 5th, a period of twenty-one days, rain fell every day, and the total rainfall for these three weeks was seven and thirty-eight hundredths inches. Trees at this period, having just finished blooming, were in a state of active growth both of fruit and foliage. Under such circumstances the unusually long period of dark, cool, rainy weather undoubtedly produced a tender condition of both foliage and fruits, rendering them peculiarly liable to injury upon slight irritation. Such irritation was produced by spraying compounds made without the ferrocyanide test as well as with it, as has already been shown. In fact, as stated by Professor Lodeman in the article cited, and as noticed by others, an unusual russetting of the fruit was found in some instances where trees had not been sprayed at all. Similar weather conditions, Professor Jones informs me, were met with in connection with his work in Vermont.

A series of careful tests in a rainy season, for the purpose of comparing Bordeaux mixture prepared according to the ferrocyanide test, with Bordeaux mixture prepared according to the old and tedious method of weighing the lime, would certainly be a very interesting line of work. We know that the ferrocyanide test has proved reliable in orchard work in an ordinary season, and as yet we have not met with sufficient evidence to prove that it is unreliable in a rainy season such as visited western New York in 1894.

By means of the ferrocyanide test, one part of copper can be detected in 400,000 parts of solution, certainly a delicate test. It is our practice, after this test shows that there is no more copper in solution, to add still more lime so as to insure an excess of that ingredient.

One gentleman reported to the writer that he had injured his Pear crop by spraying with the Bordeaux mixture made by following the ferrocyanide test. Inquiry developed the fact that he stopped adding the lime while the test still showed slight discoloration when dropped into the mixture. Unless, in the instances referred to in Professor Lodeman's article, the mixture was prepared by competent hands, it is possible that, as in the case just cited, the test was not properly used. It is admitted that when Bordeaux mixture is not properly prepared it is liable to produce injury, whether the weather be fair or foul. This may happen when the lime is weighed, as well as when a color test is followed.* If the work must be intrusted to men who cannot be relied on to follow the color test properly, it may be better to have them use the scales, slake each portion of lime by itself and patiently work it all through a gunny sack or some other strainer, according to the old-time custom, rather than depend on a color test for determining the proper amount of lime.

Forest Fires in Minnesota.

To the Editor of GARDEN AND FOREST:

Sir,—The best way to stop forest fires is to prevent them from starting. This cannot be done by enacting laws merely. The best of laws will utterly fail, unless the people see to it that they are carried out. Every person in the woods must have it impressed on his mind that no fire must be allowed to get beyond his control. This may seem a great undertaking, but when we consider that there are 20,000 to 25,000 men employed by lumbermen in the Minnesota woods, that the merchants are all studying how to perpetuate the lumber industry, and that they can get information concerning any one through the

* Note the experience of Professor Galloway, Bulletin 3, Division of Vegetable Pathology, U. S. Department of Agriculture, 1892, pp. 39 and 40.

retail stores, that all good citizens are beginning to feel the necessity of keeping every acre of forest productive of timber until it is needed for agriculture, it seems possible that now, after last season's disasters, every citizen could be brought to take an active part in this conference. I believe the time has come to start a movement that will soon establish a public sentiment that will make our forests as safe as the forests of Prussia, where only six one-hundredths of one per cent. of the forest area was burned during the very dry year of 1892. If this can be done in Prussia, why not in America?

Recent Publications.

Sweet-scented Flowers and Fragrant Leaves. By Donald McDonald. With sixteen colored plates. Charles Scribner's Sons, New York.

This work is essentially an alphabetical list of plants which are attractive on account of their fragrance. It is true, as the author states, that the professional introducers of new plants pay more attention to the size and shape and color of the flower than they do to its scent, and, therefore, it is a worthy undertaking to make this list to aid those who care particularly for the odorous qualities of plants in selecting fragrant species and varieties. The list will, therefore, prove a useful one, although many of the plants here catalogued have such a faint odor that one would hardly detect it, and, of course, it is impossible within reasonable limits to name all the plants which are pleasing to the sense of smell. We have been particularly interested in observing the efforts of the author to select words to describe the quality of a given odor. This is not an easy task—a more difficult one, indeed, than to describe a color. The only satisfactory way to do this is to say that a given odor resembles some other odor which is well known; but even this will give only an approximate idea of what is meant, since no two flowers have an identical fragrance. Turning over a few pages at random, we observe that the perfumes of different flowers are characterized as delightful, powerful, dainty, delicious, sweet, agreeable, strong, elegant, exquisite and rich. None of these adjectives, with the possible exception of "sweet," gives an accurate idea of the quality of the perfume named. Other odors are described as slight, penetrative or pungent, and these words have reference to the comparative power of odors rather than their quality. Aromatic and balsamic are words more closely descriptive. Other odors are said to be honey-like, musk-scented, lily-scented, lemon-like, or to resemble that of camphor, turpentine, mint, and these adjuncts carry some well-defined ideas. The mingling of two different colors often gives a third which resembles neither one, and some flowers are here said to have two odors, which, however, do not unite to form a third, but can be separately recognized. The flowers of *Clematis Davidiana* are said to have "a delicious fragrance of lemon and spice," a combination which we have never detected. So the fruit-buds of *Calysaccion longifolium* are said to possess an "odor like violets and rose-water," while *Asperula odorata* smells like "cowslips and new-mown hay," and *Cuscuta verucosa* smells like "violets and cowslips mixed." One can hardly understand what these combinations would be like, but still they convey some approximate idea which has more definiteness of meaning than is found in the description of the flowers of *Brugmansia suaveolens*, of which it is said that "their delicious fragrance diffuses through the surrounding atmosphere a perfume of unequalled sweetness."

The list fills one hundred and thirty-six pages, and while it makes no pretense of giving the botanical characters of the plants, the descriptions as a rule make mention of those qualities which would most interest the general reader. We ought to add, that besides the fragrance of the flower, notice is made of plants whose leaves or bark or fruits have a pleasing odor. The list is preceded by a brief treatise on the perfumes of flowers, and a few pages by way of sentimental introduction by Mr. William Robinson, editor of *The Garden*.

A Key to the Trees and Shrubs of New England. By E. Knobel. Bradlee Whidden, Boston. This booklet, which is one of a series intended to facilitate the study of natural history in New England, contains cuts of the leaves of two hundred and fifteen different trees and shrubs and climbers, and they are arranged in such a way that the identity of all the ordinary woody plants which grow in New England can be traced by the form and position of their leaves. The plan is novel, and, of course, like all keys, it is open to some objection. At the same time it will be found very helpful to beginners, who can, with a little study, locate all the native species which come under their observation. *The Ferns and Evergreens of New England* is another little hand-book in the same style, and by the same author, which contains thirty-eight figures of Ferns, besides Lycopodiums. If anything, this little key to the Filices is superior in method to the key to trees and shrubs, and it is especially good in giving, besides illustrations of the frond itself, outlines of the different divisions of the fronds as well as of their fructification. These little books are oblong duodecimos, and cost only fifty cents each; it is to be hoped that the succeeding volumes of the series, which will include notes on the butterflies, beetles, moths, fresh-water fish, frogs, turtles, etc., of New England, will be equally well done.

Notes.

Anemone blanda, *Taurian Scillas*, *Chionodoxas*, *Grape Hyacinths*, *Iris Bakeriana*, *I. histrioides*, with *Crocuses* and *Snowdrops* in variety, are now in bloom in the gardens about this city. Early Daffodils are showing buds.

The American Dahlia Society was permanently organized last Wednesday at Philadelphia, with Robert Kift as President; L. R. Peacock, Secretary; Frank C. Bruton, Treasurer, and A. Blanc, chairman of Executive Committee.

The exceptionally trying winter in Europe has done great injury to Cabbage, Kohl-rabi and Borecole planted for seed. The choice-named varieties of Celery, which are largely grown for seed in northern Europe, are also said to have been seriously injured.

Notwithstanding the fact that fresh fruits come across the continent from California by the train-load at nearly all seasons of the year, dried and canned fruits are annually exported from the same state in still greater quantities. Last year dried and canned fruits equivalent to 30,000 car-loads, or 140,000,000 pounds, were distributed throughout the world from this state.

It is objected to planting Butternuts, Hickories and Chestnuts as roadside trees, that they will be destroyed by boys in gathering the nuts. We agree with Dr. Hoskins, however, that if properly instructed the boys can be made to feel a pride in protecting what they might otherwise destroy. Why not make it a part of Arbor Day exercises to enlist the boys as defenders of the street trees in each school district?

A correspondent of *The Garden*, London, writes that at Esher Place, the residence of Sir Edgar Vincent, there is an old Tulip-tree whose stem girths eighteen feet and seven inches three feet from the ground, while its long lithe branches sweep the greensward in a circle seventy-eight feet across. The tree is in rude health, and shows no dead or dying limbs; the foliage is bright and fresh, and the flowers are produced every year "in almost extravagant abundance."

In the February issue of the *Tōkyō Botanical Magazine*, Mr. Homi Shirasaua describes, under the name of *Tsuga* (*Pseudotsuga*) *Japonica*, a tree recently discovered by him in the Province of Kii, near Yoshino. If this tree, which appears from the figure to be a true *Pseudotsuga* with shorter and broader leaves and a shorter cone than the American species, proves to be really a member of this genus, its presence in Japan is exceedingly interesting, as *Pseudotsuga*, as previously known, is confined to western North America.

A paper of considerable importance, read before the Washington Entomological Society by Professor Hopkins, of the West Virginia Experiment Station, has just been published. It seems to have been established that the potato scab and potato rot are due to bacteria and fungi, but Professor Hopkins shows that certain fungus-gnats belonging to the genera *Sciara* and *Epidapus* are able to inflict injuries upon potatoes which re-

semble the scab and rot, and since the conditions for developing the fungi are the very ones which are most agreeable to the insects, it is highly probable that much of the damage to the potato-crop is in reality due to them.

The Florida correspondent of *The Country Gentleman*, in speaking of the effects of the cold wave of February 7th on the Orange groves of Florida, says that, according to a conservative estimate, all trees under ten years old, except those in unusually favored situations, are dead to the ground or within a foot or so of it. These will have to be cut off and new trees grown from one or two of the sprouts that will spring from the live stumps. The Orange, under favorable conditions, is a vigorous grower and healthy roots will push out a sprout which, in a single summer, will form a shapely head and put out fruit-buds the second spring. In older groves the limbs up to one and a half inches in diameter are probably dead, but as the bark on the trunk and larger limbs is probably sound, these groves will be returning good returns within a decade. Of course, no one yet has any absolute knowledge of the amount of damage to the trees.

The project of making an interstate park which shall contain The Dalles of the St. Croix is advocated both in Minnesota and Wisconsin, the two states which own the land. It is proposed that 250 acres in Wisconsin and 110 acres in Minnesota shall be taken, and the property can be acquired now for a comparatively small sum. The falls are not large, but the rocky ledges which rise in an almost perpendicular wall on either side of the stream, in some places to a height two hundred and fifty feet, make a bit of highly picturesque scenery, and the gray rocks here and there stained with brilliant colors from the oxides of copper which they contain, or painted with lichens and moss, have a rare beauty of their own. The Dalles proper are about a mile in length, the river in its passage through them averaging from fifty to three hundred feet in width, with a depth of one hundred feet. It is said that a clear title can now be obtained for all the land, and it seems to be a wise plan to devote it to public use forever before its rustic beauty shall have been entirely destroyed.

In a review of the White Pine industry in the north-west since 1873 the *North-western Lumberman*, after setting forth what these great Pine forests have done in making possible the settling of southern Minnesota, Iowa and the Missouri valley, shows that from 1873, when the panic occurred which caused extreme stagnation of business, the annual pine product of that region had not reached four billion feet, and owing to the hard times that amount of production was not reached until 1879, when specie payments were resumed. Steadily increasing, the production reached nearly eight billions of feet in 1884, when it fell off a trifle, and then began to increase until 1892, when it reached the enormous total of about nine billion feet. During the last two years there has been a great decline in the output of pine, especially in lower Michigan. The production in northern Wisconsin and Minnesota is likely to continue for some years, however, and then when the decline shall become marked in that part of the field we may expect a rapid subsidence of the northern White Pine industry.

Specimens of discolored leaves of the La France Rose, grown in Philadelphia, were lately sent to Professor Galloway, of the Agricultural Department of Washington, for examination, with the request that he would determine, if possible, the cause. Replying in the *Florists' Exchange*, he suggests that since there was no fungus found, the injury may be due to the action of some poisonous vapors. This was improbable, however, since a poison vapor would naturally affect both sides of the leaf, while the disfiguration in this case was confined entirely to the upper surface of the leaves. It was, therefore, suggested that there might have been some injurious substance in the water with which the leaves were sprinkled. Professor Galloway quotes an interesting article from some German periodical, in which it seems to be demonstrated that Rose-leaves in an outdoor garden were injured by vapor from asphalt which was washed out of the air by falling rain and dropped upon the foliage. Careful study seemed to prove that the slight quantity of iron held in the vapor in the form of iron salts caused the trouble. Of course, the quantity must have been exceedingly minute in this case, and, therefore, it may be possible for an almost infinitesimal percentage of iron in water used upon plants to bring about this discoloration, which is caused by the precipitation of the tannin held in the sap of the leaves. Begonias and other plants which contain no tannin, when subject to the same conditions, received no injury.

The season for Cuba pineapples, which opens here about the middle of April, is already anticipated by advance lots of this fruit in shipments of 100 to 300 barrels. As many as 27,000 barrels arrived in a single week during last May. The variety now beginning to come is the Red, or Strawberry pineapple, and this will be in season here until the last of June. It is most abundant and in best condition in May, when it is in greatest demand for preserving and for making extracts, its rich flavor rendering it specially suitable for this use. The Sugar-loaf pineapple, which comes early in June, continues through July. Good pineapples now cost twenty-five to thirty-five cents each at retail. Florida oranges seem to hold a place entirely their own, for even the shortage of 2,000,000 boxes of this fruit has not made any extraordinary demand for other oranges, or materially increased their prices. Seedling oranges from California sell as low as \$1.50 a box at wholesale, and from this the merchant must deduct ninety cents for freight charges. Navel oranges sell at \$2.75 to \$3.25 by the box. Sicily oranges have been selling at serious loss to importers, and fruit which cost \$1.87 a box in Sicily, with expenses for cartage, insurance, commission, etc., to be added, is sold here at auction for \$1.25 to \$1.75, which means a loss of fifty to seventy-five cents a box. Nearly 44,000 crates of cranberries had been received in this market at this time last year, and about as many crates have been handled here this year, but only 25,000 barrels, as against 51,000 barrels a year ago. The price this season reached \$14.00 a barrel at wholesale, fully double that of ordinary seasons.

Another of the Nestors of American botany has gone. This time it is Isaac Sprague, for nearly half a century the most skillful and prolific botanical draughtsman in America, who died at his home in Wellesley Hills, Massachusetts, on the 15th instant. Isaac Sprague, the son of Isaac Sprague and his wife, Mary Burr, was born in Hingham, on September 5th, 1811. His father, a cooper by trade, was an intellectual man; his mother was known for her remarkable judgment and common sense. The younger Isaac Sprague served his apprenticeship as a carriage-painter with an uncle, spending his holidays and spare hours learning to draw and paint. In 1834, having come into possession of a copy of Nuttall's *Ornithology*, he began to study birds, all his leisure moments during the next ten years being devoted to making himself acquainted with their habits and structure, and in drawing birds and plants. In 1840 Audubon came to visit a friend at Hingham and was much impressed with Sprague's bird pictures, and three years later, at Audubon's request, he passed a month with him in New York, which led to his being invited to join the great naturalist in an expedition to the upper Missouri to assist in making drawings and sketches. A lark discovered during this expedition was named by Audubon Alauda Spraguei. In 1844, at the request of Professor Asa Gray, Sprague visited him in Cambridge; beginning about this time his botanical work, with drawings, for Gray's *Text-book of Botany*, and a series of large botanical charts used by Professor Gray to illustrate a course of lectures in the Lowell Institute.

In 1845 Sprague established himself in Cambridge and devoted his time to scientific work. At this time he made the very successful outline drawings for Mr. Emerson's *Trees and Shrubs of Massachusetts*, a work which, in a second edition, he illustrated at the end of his active career with beautiful colored drawings. In 1848 the first volume of Professor Gray's *Genera Flora Americae Boreali-Orientalis*, a work intended to illustrate the genera of North American plants, appeared. Unfortunately, lack of support brought the undertaking to a close at the end of the second volume; the plates, two hundred in number, were drawn in outline by Mr. Sprague with elaborate analytical details and were far superior to any botanical drawings that had been made in America at that time. They must be considered Sprague's most important work and are still models of their kind. His pencil illustrated Torrey's *Plantæ Fremontianæ*, and all of Dr. Gray's classical memoirs on the plants collected by Charles Wright and others on the southwestern borders of the United States, and his report on the plants collected in the Wilkes Expedition. His published plates give, however, but a slight idea of Sprague's industry, and he has left portfolios filled with drawings of birds, insects and plants, and innumerable sketches.

Spraguea, a beautiful little herb of the foothills of the Sierra Nevada, was dedicated to him by Torrey in token of the appreciation the masters of botanical science in America held for this modest, retiring and industrious man, a true naturalist and lover of nature, to whose skillful pencil much of the value of their work was due.

Why We Need Skilled Foresters.

A FORTNIGHT before the adjournment of the last Congress, Mr. Fernow, Chief of the Division of Forestry in Washington, appeared before the House Committee on Agriculture and presented a statement in regard to some proposed legislation for the establishment of courses of forestry in agricultural colleges and the establishment of a national school of forestry. In regard to the special provisions of the two bills under discussion we shall take occasion to speak at another time, but just now it is our purpose to reproduce in a condensed form some of the arguments presented by Mr. Fernow to show why we ought to begin at once to provide for a supply of technically educated forest-managers. The shameful annual waste of our forest resources is due to a lack of knowledge of even the elementary principles of successful forest management, and the waste will continue until the necessity for greater knowledge is realized. This broader knowledge will surely arouse us to attempt the management of our public and private forest-lands on rational principles, and then the demand for skilled foresters will be urgent.

The forest area of the United States is the country's largest producer of value, except its agricultural lands, and these yield their return with much hard human labor, while our forests give their enormous quantity of material, exceeding in value a thousand million dollars every year, for the mere harvesting. Our forests, while yielding twice as much as all our mines of every kind, have been worked as if they were mines, and they have even been mined irrationally. Not only has the accumulation of centuries been taken away with no thought of future production, but the paying ore has been taken out and the tailings have been dumped on the remainder to make its development more difficult—that is, not only have the forests been slaughtered without any attempt to provide for growth in years to come, but the useful species have been culled out and the grounds have been left to inferior kinds to grow up and prevent the natural reproduction of the better kinds, and in this way the value of large areas of growing timber has been impaired.

According to Mr. Fernow's estimate, we have reduced our supplies to a point where we are cutting into our capital at the rate of fifty to seventy-five per cent. of our con-

sumption every year—that is, it is probable that the annual growth of the timber in the United States does not amount to more than a quarter of the wood we cut and use in any year. Of course, a change from these irrational methods ought to have been made long ago. That such a change should be made before our supply approaches any nearer to absolute exhaustion may be understood when we remember that many of the trees we are now cutting are centuries old. The desirable pine lumber of Michigan and of Wisconsin began to grow in the time of the French and Indian war; the hard Pine of the south must be two hundred years old or more to satisfy a lumberman. The Spruces of Maine furnish comparatively little saw-timber before that age, and the big Tulips and Cypress and many of the Oaks of the south, together with the magnificent giants of the Pacific, count their age by centuries. Our statistics are of the crudest, and it is useless to speculate how long our forest resources will last under the present methods of using them, but if these methods are not changed it is safe to say that a scarcity in desirable wood material will be pinching us within the next half century—that is, before a new crop can mature. Of course, we shall not stop or even materially reduce our consumption of wood until the necessity is at our doors, for it is the experience of the world that, in spite of substitutes and changes of condition, wood is so useful and indispensable to civilization that its total consumption does not abate. All this shows more than a lack of forethought. It shows among the people most interested an utter ignorance of the fact that the timber growing on an acre of land is a crop, and that it ought to be treated as a crop, just as Wheat or Corn is treated; that the growing of timber may be carried on as a business, and that this business requires skill and knowledge; that in our natural forests timber cutting and timber growing can be carried on at once, and that by a judicious use of the axe alone in old timber, a new crop of better quality and larger quantity to the acre can be reproduced.

There is no need to enlarge here upon the fact that in the south thousands of square miles have been made practically useless by erosion, which is directly traceable to the destruction of the forests there, nor upon such other established truths of general interest as that the destruction of forests intensifies floods, wastes the water which should be stored up for irrigating our plains, and injures crops and climate by allowing fuller sweep to drought-bringing winds. The need of preserving an assured supply of forest material is of itself enough to justify any effort at increasing the knowledge of practical forestry. That the agricultural colleges ought to be required to give some instruction on a subject so intimately related to the cultivation of the soil seems to need no argument. Many of the sciences on which agriculture is based must be studied by the skilled forester, and, therefore, these colleges are partially prepared to furnish the needed instruction. Several of them already do furnish instruction of a rudimentary and primitive character, but, until there are special chairs of forestry established, we can hardly hope that much technical education which will fit a man to manage forest property intelligently will be given. How men can be found to fill these chairs is a question to be discussed by itself, but, certainly, this educational problem is that part of the general forest problem which just now demands the closest study.

The Farm Home Reading Circle.

IN the latter part of the year 1892 the Faculty of the Michigan Agricultural College prepared a course of reading for farmers, gardeners, fruit-growers, stock-breeders, etc., to be used in what is designated the Farm Home Reading Circle. The object of this reading circle was to offer a systematic course of reading on agriculture and kindred topics, with books furnished at reduced prices through the Secretary, and provision was made by the State Board of Agriculture to have the printing, correspondence

and postage free, so that the books would be the only expense to members. Persons of any age were invited to join the circle. They were all entitled to the publications of the state experiment station, and they were encouraged to address questions on any doubtful points to the faculty of the college. When any reader completed a book he could obtain a blank from the secretary and make a written report on the leading topics of the work, and if this was satisfactory he was entitled to a written voucher which certified to this fact; when all the books in any one course, whether relating to the garden and orchard, to live stock, to soils and crops, or to any other special subject, was completed, the reader would be entitled to a certificate of the next grade, and on the completion of any three courses a diploma was to be issued.

Professor Mumford, who is the secretary of this circle, writes that it has met with unusual success. Three hundred readers are pursuing their work now, more than a thousand inquiries have been made, and twenty-five hundred persons have asked for circulars. In experience the course seems to be cumulative, and as one person reads a book he recommends it to a friend, who likewise reads it, and thus the circle widens. Expressions of appreciation have been received from influential farmers in many states, and from every evidence the course has begun a career of genuine usefulness. There can be little doubt that an organization of this kind will prove a genuine help to agriculture. The short courses in many of the colleges, schools of dairying, farmers' institutes and horticultural assemblies, like the one recently held in Chautauqua County, will accomplish a genuine service, even if they did no more than to bring farmers into contact with men of science, either personally or through books, and convince them that there is such a thing as scientific truth, upon which the best practice is always based. The young man, or woman, who reads a few books, will not be an accomplished practitioner in any branch of agriculture or horticulture, but if he is able to pass examinations in these works he will learn the value of study and mental application, he will learn how to think consecutively about his business, and he will know where to turn for information when he needs it.

The White Pine in the West.

THE White Pine has a peculiar record in the west. In Illinois and the greater part of Iowa it is one of the most satisfactory conifers that can be grown. I know of no tree anywhere that surpasses in symmetry and vigor a splendid White Pine-tree in the old James Smith homestead, south of Des Moines—a tree that was over fifty feet high when I last saw it, several years ago, and there seemed not a branch missing from its widely spaced, regular whorls. Along the Missouri River, in Kansas and Nebraska, White Pines can be found as vigorous and thrifty as any planted specimens anywhere. At the home of Hon. J. Sterling Morton, Nebraska City, are a number of White Pines of unusual beauty, the best of which is forty-nine and a half inches in circumference three feet from the ground, and forty-four feet eight inches high. Mr. Morton planted this tree thirty-two years ago, carrying it to its place in a water-bucket. It is thus seen that the White Pine grows as rapidly in the clayey bluffs of the Missouri River as in the sandy soils of Michigan. At Lincoln, Nebraska, only sixty miles back from the Missouri River, the White Pine is not a success. At Fairbury, almost due south of Lincoln, it does not compare with the other Pines, while at Franklin, more than half-way across the state, a few specimens have barely managed to exist during several years, in which the Scotch and Bull Pines have made vigorous growth. Nowhere back from the Missouri did I see vigorous trees, except at Salina, Kansas, where there are two good specimens twenty-four feet high, but these do not compare with the White Pines at Nebraska City, nor with the Scotch and Austrian Pines growing near them.

At Brookings, South Dakota, the same care that gave satisfactory results with Scotch Pine produced nothing but complete failure with White Pine. Five hundred transplanted trees, from ten to fifteen inches high, were received in fine condition, and were grown one year in nursery, being mulched during the hottest months. Very few died, but no appreciable growth was made. Good buds were formed, however, and the next spring they were set in forest-plots with White Birch and Box Elder. In three years not a Pine remained.

It would seem, then, that White Pine is not a promising species for planting much beyond the Missouri or in Dakota. In all the northern part of Missouri the White Pine can be successfully grown. At Columbia, half-way between St. Louis and Kansas City, and ten miles north of the Missouri River, there is a splendid avenue of White Pines on the old Rollins homestead, which average fifty feet high and show most satisfactory growth. Doubtless, the increasing aridity of the atmosphere west of the Missouri River is the reason of the failure of the species in that locality.

Washington, D. C.

Charles A. Keffer.

Marketing Apples.

SOME essential points to be considered in the marketing of fruit were given by Mr. George A. Cochrane in a paper read a few weeks ago before a meeting of the Massachusetts Fruit Growers in Worcester. We quote in a condensed form a few paragraphs, which will be found interesting to buyers as well as growers :

For several reasons the barrel is too large a package for apples, which should be marketed in boxes no larger than those used for oranges and lemons. Last fall I advised the trial of such a package, and suggested that each apple be wrapped in paper as oranges and lemons are. Three thousand cases were sent to me for shipment to Europe. Out of fifty growers of apples only three understood what a close selection of fruit meant, and the apples sent by these three growers sold in London at \$2.40 a case, when fruit in a barrel, which held three times as much as one of the cases, brought only \$4.00. Some growers sent windfalls, in the hope that wrapping them in paper would insure their safe arrival in England. Some sent Snow apples and Russets mixed in the same case. Of course, when barrels are used, new ones, and not second-hand flour-barrels, should be used, for, no matter what care is taken to dust and wash them, sufficient flour will remain in the seams or staves of old barrels to rattle out in transportation and dust the fruit.

In packing a barrel select a fair sample of the contents for the bottom layer. Place the apples, stems down, in the form of a ring, beginning at the outside, and having secured this layer firmly, place the second layer in so as to fit closely in the interstices, then fill the barrel quickly and gently, and when one-third full rock it slightly to settle the apples. Repeat this rocking when the barrel is about three-fourths full, and when it is filled place a padded board on top and rock it while the board is held down firmly. Then place in enough more apples to form a cone at least two inches above the chime. Now force the head down with a barrel-screw presser, nail the chime hoops, both top and bottom, securely, and have the head-lining sufficiently large to lap the presser that forms the head.

Never pack red apples until they are of a good color. It is an expensive blunder to wait until the last moment and then strip the tree of all its fruit. It is also a mistake to pick the apples faster than they can be packed. It is a good plan to go over the trees a week or a fortnight before the general picking and remove the well-developed and well-colored fruit and market it at once. Aside from the advantage of early marketing, such pickings help the fruit which remains, increases its size and improves its color. Apples should be headed up at once, and if they are to be held they should be hurried into cold storage as near a temperature of thirty-two degrees as possible. They should never be allowed to lie on the ground, and under no circumstances should they be exposed to sun or rain after being picked or packed. Fall varieties decay quickly, because they are exposed to a higher temperature after leaving the tree than the winter varieties are, and more fruit is lost after being picked in the heat than from the frost. Growers who keep apples in bins to market during the winter should

select and sort at the time of picking. Only perfect and healthy fruit should go into such bins. Cellars should be ventilated so that advantage of any change in the temperature can be taken and the fruit kept as nearly as possible at the required coolness. When the average temperature has been above forty-five degrees from the time of sorting up to December 15 apples should be marketed as soon after the turn of the year as possible. When they are kept in the bin after this time they will not stand rough usage and will not answer to ship to Europe in barrels. One reason why fall fruit does not pay arises from the fact that large quantities of delicate fruit is placed in one compartment, which, because it is air-tight, becomes overheated. Such delicate fruit ought never to be placed in barrels, except for near-by markets, and then only under the most favorable conditions of weather. Were American apples marketed in as sound condition as oranges are, if they were graded as oranges are as to quality and size, if they were wrapped and packed as oranges are, they would be worth three times as much as they now command in Liverpool.

Foreign Correspondence.

London Letter.

ASARUM MAXIMUM.—The genus Asarum has not hitherto claimed much attention from horticulturists, but *A. maximum*, now in flower at Kew, is certain to become generally liked on account of the large size and beauty of its flowers. It was first described by Mr. Hemsley, in *The Gardeners' Chronicle*, in 1890, from specimens collected in central China by Dr. Henry, who stated that it occurs in glens about Ichang Gorge on sides of cliffs, always some distance up, and that it is called "Ma-ti-hsiang" by the Chinese, who use the root medicinally. Mr. Hemsley described it as the largest of the genus known, the leaves being as much as eight inches across and eighteen inches high and the flowers two and a half inches in diameter, dull green, colored outside dark maroon-purple and velvety within, with a three-lobed conspicuous eye-like blotch of white surrounding the mouth of the tube. Except that the leaves are smaller, this description fits the plant now flowering at Kew. The leaves are not unlike those of *Cyclamen* in form and substance. In some species of *Asarum* the flowers have a strong aromatic odor, which is distasteful to some people, but *A. maximum* is odorless. The Kew plant was received from Hong Kong last year, and it has been grown in an intermediate temperature along with *A. macranthum*, *A. geophilum*, *A. Thunbergi* and *A. caudigerum*, all of which are natives of China. The genus *Asarum* is allied to *Aristolochia*. About a score of species are known, all of them being dwarf, with creeping rhizomes, cordate leaves, and short-stalked flowers, which are developed from the axils of the leaves, generally in tufts, the perianth being fleshy, tubular, with three broad spreading lobes. A figure of *A. maximum* has been prepared for the *Botanical Magazine*.

SHORTIA GALACIFOLIA.—This is not merely a botanical curiosity; when well grown it is a very pretty plant, quite equal in attractiveness to many of our most popular alpines. This week a plant of it was shown from the garden of Lady Bowman, Joldwynds, Surrey, which was awarded cultural commendation by the Royal Horticultural Society. It was in a pan nine inches in diameter, and was a large tuft of healthy green, brown-tinted leaves, from which sprung over fifty flower-scapes, each six inches long, many of them bearing a pair of open flowers. The bell-shaped corollas were an inch long and wide, white, with a pale flush of rose. Mr. Cornish, Lady Bowman's gardener, who is a clever cultivator of herbaceous and alpine plants, grows the *Shortia* in a mixture of sandstone and peat and keeps it in a cold frame, where it is sheltered from bright sunshine during the summer. We owe the *Shortia* to the Alleghanies, and possibly it is grown in American gardens better even than at Joldwynds; if not, then it is certainly worth trying.

VIBURNUM RUGOSUM.—This is the *Laurestinus* of the Canary Islands, whence it was introduced into English gardens

about a century ago and is still in cultivation here, though sparingly, as a greenhouse plant. It deserves to be better known, as it forms a sturdy shrub, is evergreen, its leathery, corrugated ovate leaves being five inches long and covered with a ferruginous down. The flower-heads, which are terminal, are like those of the common *Laurestinus*, but much larger, being four inches across and densely packed with pure white flowers, in which the pink stigma is an additional charm, and the odor powerful and agreeable. Some plants of it at Kew, raised from cuttings rooted two years ago, are now nice little shrubs two feet high, with fine heads of bloom, and they have been in flower several weeks. In places where this plant could be grown in the open air it would be an excellent spring-flowering shrub.

EUCHARIS STEVENSII.—Examples of this plant were exhibited last Tuesday and obtained an award of merit. It is said to be a hybrid between *Eucharis Sanderi* and *E. candida*, and it closely resembles the former, which Mr. Baker believes to be a natural hybrid between *E. candida* and *E. grandiflora* (*Amazonica*). The flowers of *E. Stevensii* are of medium size, and they are borne on long scapes, the plants flowering freely. It was first flowered in 1885, when it was supposed to be *E. Mastersii*, a species introduced by Messrs. Sander & Co. from New Granada in 1885. The plants shown last Tuesday were from the garden of the Duke of Sutherland at Trentham. They were in five-inch pots, and each bore one or two strong scapes of bloom. There is one grand *Eucharis* and about half a dozen others, which would be considered first-rate were it not for this one, namely, *E. grandiflora*, the most useful of all tropical bulbous plants. The habitat of this *Eucharis* is still unknown.

BEGONIA, PAUL BRUANT.—I noted this useful hybrid as being in flower at Kew in February last year. This year it is later, a group of it being at its best now, the middle of March. The plants were struck in the summer of last year, and they are now a foot high, and bear large drooping clusters of elegant pale pink flowers, which remain fresh on the plant for several weeks, as they are nearly all female. There is a good picture of this *Begonia* in the *Gardeners' Magazine* for this week.

BEGONIA, GLOIRE DE SCEAUX. is much better this year than it has ever been, plants nearly a yard high being clothed with shining bronze-tinted foliage and bearing large erect trusses of rose-pink flowers. It was figured in *GARDEN AND FOREST* last year, page 185, the plant represented there, however, being small compared with those in flower now at Kew. I consider this one of the best of the winter-flowering Begonias and one of the most distinct. It is one of the now numerous progeny of *B. Socotranica*.

THREE GOOD GREENHOUSE PRIMULAS.—In the conservatory at Kew there are now groups of many kinds of spring flowers, and three of the most attractive are composed as follows: (1) *Primula floribunda*, rich yellow, and the double Chinese *Primula*; (2) *P. verticillata*, pale yellow, and *Lily-of-the-valley*; (3) *P. obconica* and red single Chinese *Primula*. A pleasing effect is obtained by arranging the plants in groups composed of one or two distinct things, much more so than when the plants are mixed indiscriminately. There is no need to recommend *P. obconica* as a garden-plant. It is a beautiful and most useful early spring-flowering plant for the conservatory. *P. floribunda* is not so well known. It was introduced to Kew from the Himalayas in 1883, and has been grown here ever since. Treated in the same way as *P. obconica*, it forms compact leafy plants in five-inch pots, the whorled leaves bright green, and the flowers crowded on erect scapes nine inches high, their color rich egg-yellow, and, although only half an inch across, they made a good show. *P. verticillata* is the third good greenhouse species, which is not generally grown. It forms a tuft of leaves nine inches across, something like *P. vulgaris*, but thinner, more distinctly toothed, and the surface covered with whitish flour, as in *P. farinosa*. The flower-stems are a foot high, and they bear several whorls

of leaves and two or three whorls of flowers, strong stems having twenty flowers in each whorl; these are semi-drooping, and have a tube over an inch long, a limb half an inch across, their color being primrose-yellow. Plants of these in five-inch pots are very decorative when in flower. At Kew these three Primulas are raised annually from seeds, and grown in frames along with and treated the same as *Cyclamen Persicum*. *P. verticillata* is a native of Arabia, although it is called the Abyssinian Primrose in gardens.

VIOLET, PRINCESS BEATRICE.—This is a new Violet, which was shown last Tuesday from the Queen's garden at Osborne, Isle of Wight, and received an award of merit. It is the largest-flowered Violet grown here, the flowers being an inch and a half across, the stalks nine inches long, and the leaves three inches in diameter. Its color is rich blue-purple, brighter than the color of Victoria, which was also shown, and its fragrance quite equal to that of any of the big-flowered Violets. Mr. Nobbs, the gardener at Osborne, says that he found this new Violet growing in an uncared-for part of the garden, and that Her Majesty, who is fond of Violets, prefers it to all others, and desired that it should bear the name of Princess Beatrice. I have not seen the new American Violet called California, but those who have say it is very similar to this royal waif. There is an enormous trade done in Violets in England in the first four months of the year, as they are universally popular with flower wearers. The large-flowered, bright-colored varieties find most favor with ladies.

STRAWBERRY, STEVENS' WONDER.—This is a new variety which obtained a first-class certificate last Tuesday, when Mr. Stevens, a Sussex nurseryman, exhibited plants of it in pots and bearing exceptionally large crops of large, handsome, well-colored, highly fragrant fruit, which in form may be described as intermediate between Noble and Sir Charles Napier. The leaves are small, dark green, with short stalks, and the fruit-stalks short and firm. Mr. Stevens had plants of it in full bearing on February 21st, when he sold the fruit to Mr. George Munro, the Covent Garden salesman, at six dollars per pound. I saw a letter from Mr. Munro, in which he stated that this Strawberry was the best for early forcing that he had ever seen, as the fruit was large and of good flavor. The pale color would, perhaps, be against it later in the season. Some plants grown in six-inch pots produced from twenty to thirty fruits, the largest being one and a half ounces in weight. Growers of early strawberries reckon that there is sure to be a large demand for Stevens' Wonder.

London.

W. Watson.

New or Little-known Plants.

*Mimulus Clevelandi.**

THIS species (see figure, page 135), one of the handsomest of the genus, was found on the south side of Cuyamaca Peak, in southern California, not far from the signal station on its summit. It grows in patches, spreading by underground roots. Among loose rocks the stems attain a height of two feet, but on exposed slopes their length is considerably less. Although growing at a much greater elevation (over 6,000 feet) than *Mimulus glutinosus*, its stems are woody, though short. It connects that species more closely with the sections *Enoe* and *Eunanus*, which have in most cases the same dehiscence. It is now in cultivation in San Diego, and it will be of interest to observe

* *Mimulus Clevelandi*, n. sp. Perennial, suffrutescent at base, 3-6 dm. high, glandular-pubescent throughout; stems many from the base, sparingly branched above; leaves lanceolate, serrate, 3-7 cm. long, narrowing to the clasping base, in age revolute on the margins; flowers shortly pedicellate; calyx 2 cm. long, contracted above the ovary, the upper and longer portion curved and spreading, the lanceolate, somewhat unequal teeth $\frac{1}{2}$ the length of the tube; corolla golden yellow, nearly twice the length of the calyx, with gradually dilated throat and widely spreading nearly equal lips; style stout, minutely and densely glandular; stigma tubular-peltate; mature capsule 10-12 mm. long, nearly quadrangular, tapering slightly toward the apex, opening to the base by the upper suture, the lower separating for only a short distance from the tip, and each valve splitting at the tip for nearly the same distance as the lower suture; placentæ separate, as in *M. glutinosus*; seeds foveolate, apiculate at both ends.

whether its stems become longer or larger in this milder climate.

The species is named in honor of Mr. Daniel Cleveland, whose name is so well known in connection with the flora of San Diego County.

San Diego, Cal.

T. S. Brandegee.

[Judging from herbarium specimens, this *Mimulus* ought to be a good ornamental plant in California or southern Europe. Of course, it would not be hardy here, and it is hardly probable that it would make a good greenhouse plant, but, in dry climates, where it could be watered, it might become a large shrub and flower throughout the year.—ED.]

Plant Notes.

LEUCOJUM VERNUM.—Although not one of the very earliest spring-blooming bulbs, this Spring Snowflake, as it is familiarly known, in favorable situations follows closely the Snowdrops and Crocuses. It is like a very large Snowdrop; the white flower, with yellowish green tips to each petal, is graceful and charming. It should be planted in clumps, in well-drained soil, in a sheltered place, and not disturbed after it has once become established. Although long in cultivation, the Spring Snowflake is by no means common in American gardens, probably because it is not so easily handled as most bulbs, and does not thrive except under the conditions noted above. The bulbs are cheap and easily obtained.

STROBILANTHES DYERIANUS.—This new bedding-plant belongs to the Acanthus family, and is one among its many plants remarkable for bright-colored foliage. It is nearly related to the better-known Goldfussias and Ruellias, but is of no value as a flowering plant. It is soft-wooded, having the thick nodes that characterize the order; stout, erect stems and opposite leaves. When kept in vigorous growth the foliage is remarkably beautiful, of a rich iridescent purple, with green veins, and slightly suffused with steel-blue. The plant, however, if left alone soon runs into flower and then becomes ragged and shaggy. The flowers are individually quite pretty, about an inch long, labiate, almost regular, and pale blue in color. The inflorescence is a loose-bracted spike, rather large, but not pleasing in appearance. The chief value of this new species is, therefore, as a foliage-plant, and then only for outdoor use. Whether or not it will prove superior to the darker varieties of Coleus as an effective bedding-plant remains to be seen. It will probably form beds of a more striking and characteristic appearance, and doubtless deserves a good trial. The culture is very easy; cuttings may be rooted in a brisk bottom-heat in two or three days and when potted in rich, fibrous soil, and kept warm and moist, they will grow rapidly. Plants can be propagated by cuttings, like Coleus, or by means of single eyes, with a leaf attached. As the leaves are opposite, the stem may be split, and two cuttings made of each node. This method, by which a larger number of plants can be made from limited stock, is very good, but a single eye will not produce a plant as rapidly as a growing top.

BEGONIA FEASTII.—A Begonia is occasionally seen in the gardens of the eastern states labeled with this name, although it is sometimes grown under other names, or with no name whatever. In a note about this plant, which he considers the most useful of the winter-flowering kinds, on account of the ease with which it is grown and its neat compact habit, Mr. Michael Barker, of Cornell University, says: "I am now well satisfied that it is a hybrid of American origin. I do not remember to have ever seen it in European gardens, and it is not catalogued by any of the European dealers, at least as *B. Feastii*, and I have never been able to find a figure of it. The only references to it which I know are two slight ones in *The Gardeners' Monthly* for 1885. It is there said to be a hybrid, raised by the late John Feast, of Baltimore, Maryland, from the old species, *B. hydrocotylæfolia*, as one of its parents, but the other

does not appear to have been known. The stems are thick and spreading and well furnished with prominently veined leaves, deep green on the upper surface, and reddish be-

suppressed; but, from a decorative standpoint, the broad-winged ovaries make up for all other deficiencies. The ovaries proper are of greenish white color, the wings and

Fig. 20.—*Mimulus Clevelandi*, n. sp.—See page 134.

neath. The staminate flowers are inconspicuous, dropping from the plant at an early stage of their existence; but the pistillate blossoms are better developed, showing perfect stigmas and two small orbicular sepals. The petals are

sepals bright pink." Mr. Barker sends a photograph of this Begonia in flower, which shows a plant of neat and distinct habit and graceful inflorescence. We should be glad to receive any additional information as to its history.

Cultural Department.

Some Flowering Plants for Easter.

MOST private greenhouses are called upon for flowering plants for church, house or conservatory decorations at Easter-time. This year the date is later than for several seasons past, and a good deal of forethought and judgment is required to have some varieties in flower at the right time. Easter Lilies are the most important crop, and one of the most difficult to have in condition at a required time. As a rule, if the buds just begin to show when Lent begins the flowers will be on time without forcing the plants unduly. By hard forcing we have had plants flower in March, even when the buds were only seen four weeks before Easter. If brought on in an ordinary greenhouse temperature, six weeks is not too long a time to allow, even if the plants are not needed until the middle of April. *Lilium longiflorum* requires fully a week longer to develop than *L. Harrisii*; *L. candidum* taking about the same time as the last named. We use eight-inch pots of Lilies. The largest bulbs are grown singly, while the small ones are placed three in a pot. The average product of the larger bulbs is from eleven to fifteen flowers, while the smaller ones produce from six to nine flowers.

The herbaceous Spiræas are indispensable Easter plants. They should be allowed from eight to ten weeks for flowering after they are potted. *Spiraea Japonica* is still more largely grown than any other variety, but its variety, *Grandiflora*, now that it is becoming cheaper, will largely supersede the older plant. When well grown, it makes a beautiful pot-plant. *S. astilboides* forces very readily, but it has not the compact habit of the other two varieties. It grows much taller, and is worth growing for variety. *S. palmata* we do not find satisfactory. Spiræas should be removed from the house or stood on the floor and covered with paper while the place is fumigated, as the foliage is very easily scorched, and large numbers of plants are ruined every year through neglect of this precaution.

Hydrangeas, especially *H. Otaksa*, make admirable Easter plants. We began to force our plants at Christmas, and the flower-heads will be well expanded early in April. Cuttings inserted early in February and potted off when rooted, if planted out-of-doors toward the end of May, and watered during droughty weather, will be fit for eight-inch pots in September. Such plants give from eight to twelve good panicles each, and cuttings rooted later in the season will flower well. Plants grown in pots all the season and plunged in a bed of ashes have not proved as successful with us as those planted out.

Azaleas are among the most popular of Easter plants. Owing to the lateness of Easter this year, it is impossible to hold back some varieties, notably the beautiful double kind, *Ver-væniana*, but *A. Borsig*, double white; *Impératrice des Indes*, double rose, edged with white; *Sigismund Rucker*, rose-pink, bordered white, dark blotch; the magnificent *Madame Van der Cruyssen*, rose, with spot on upper petals, and one or two other kinds will be in season if held in a house with a northern exposure or in a cold frame until a few weeks before they are needed. Plants of *A. mollis* are among the best forcing plants, and a few of these are always a welcome addition at Easter.

Cytisus, in six to eight inch pots, which have been clipped into shape during the growing season, and held back in a cold house, make excellent Easter plants. *Cytisus racemosus* is much superior to the older *C. Canariensis*. Some kinds of more recent introduction have much larger racemes, notably *C. elegans*. The flowers, however, are produced less freely than on the older sorts.

White Marguerites, or Paris Daisies, are very useful for church or conservatory decorations, and cuttings inserted in October, if grown along in an ordinary greenhouse, will make fine bushy plants in eight-inch pots by Easter-time. The variety *Maximum* is the most serviceable; the yellow-flowering varieties, *Comte de Chambord* and *Etoile d'Or*, flower unsatisfactorily, and are rather straggling in habit.

Deutzia gracilis is one of the best forcing shrubs and can be quickly pushed along at this season. Cuttings of soft wood strike very freely, and make nice plants if planted out for two years. The plants, when of sufficient size, should be grown along in pots all the time and plunged during summer in a bed of ashes. Plants dug out of the ground, potted and forced, yield plenty of bloom, but the quality of the flowers is inferior to that of pot-grown plants.

Callas are always in large demand for Easter, and the old *Richardia Æthiopica* is still altogether the best. The variety, Little Gem, so loudly praised, can hardly be called a success as a winter bloomer. Until the middle of February our plants

hardly showed a flower, and while it is now blooming fairly well it does not equal the old variety in its free-flowering qualities. Many growers have become discouraged with Little Gem and have discarded it entirely, but a few plants well flowered are quite effective in decorations.

Some of the Begonias, especially the Manicata section, will be in good bloom for Easter this year, and are certainly beautiful when well flowered. *B. semperflorens gigantea*, with its brilliant carmine-red flowers, borne in large panicles, is one of the finest of its class. From cuttings inserted now large bushy plants can be had for next winter. Planted out in a partially shaded border, all the fibrous-rooted Begonias do well in the summer, and if carefully lifted and potted in September sustain very little check.

Easter generally comes too early for the flowering of fancy Pelargoniums, or Lady Washington Geraniums, as they are commonly called. This year a number of our plants promise to be in good bloom. No soft-wooded plant equals in beauty a well-flowered Pelargonium, and it is satisfactory to note that they are gradually coming into popular favor again. Cuttings rooted in September and potted and grown along in an ordinary greenhouse, make good plants in six-inch pots at this season; older plants cut back are, however, preferable. Good varieties are *Volonte Nationale alba*, *Mrs. R. Sandford* and *Princess Teck* for white; *Madame Thibaut*, a beautiful rosy pink, and *Kingston Beauty*, white, with maroon blotch.

Cannas, potted in the fall when the roots are lifted from the beds, are capital winter-flowering plants and make a brilliant show at Easter. We grow our plants in eight or ten inch pots in a moderately warm greenhouse. *Madame Crozy* is still the best of this family as a pot-plant; *Alphonse Bouvier* and *Charles Henderson* are good of their color, the first-named being the most satisfactory winter bloomer here. *Florence Vaughan*, although not a free winter bloomer, is now in full flower.

Cinerarias will be mostly spent before Easter-time, but herbaceous Calceolarias more than make good this deficiency, and well-grown plants are highly decorative. White Stocks are useful plants, and for decorations we use the kind known as Boston Florist. Antirrhinums make good pot-plants and can always be had in flower for Easter. Bulbous plants, such as Hyacinths, Tulips and Narcissus are always popular, and very little forcing will be needed this year to have them in flower. Two of the most useful Orchids at Easter-time, *Cattleya Trianae* and *Cœlogyne cristata*, are now on the wane. Plenty of material is available among Odontoglossums, Cattleyas and Lælias, to say nothing of other genera of Orchids, to make a good display, where these plants are grown.

Taunton, Mass.

W. N. Craig.

Japanese Anemones.

THERE is no more suitable plant for piazza, porch or hall decoration than the Japanese Anemone. As a pot-plant it is unexcelled, and fully repays any extra attention given to it. Though generally grown as a hardy perennial, it is not entirely successful as such. The flowering crowns are frequently destroyed during severe winters; but, as every piece of root develops adventitious buds in the same way as our native *Anemone Pennsylvanica*, the plants are seldom killed outright, and will shoot up again later in the season, but generally too late to make strong blooming crowns before frost. By storing our plants in a cool cellar we avoid this drawback; and as they do not lift well when planted out, we find it better to repot them every year. We shall overhaul our plants in a few days, potting them in good heavy loam and well-decayed manure in the proportion of one-third of the latter. We use twelve-inch pots, as our clumps are large, containing eight to ten crowns. Small plants, such as are obtained from the dealers, might be put three together in eight-inch pots, making effective plants by the autumn, and these would be large enough for twelve-inch size next season. It will be found in repotting old plants that they have in the course of the previous season made a number of fleshy underground stems. These had better be trimmed off, for if left they will grow and fill up the pot with a lot of useless growth, impoverishing the soil. These stem-like roots develop plantlets from every bit, and so, if any stock be required, it would be well to make a thin layer of them in boxes, with a covering of sandy loam. This is the way the dealers obtain their stock. If, after being potted, the plants are put into cold frames and encouraged by husbanding a little sun-heat the latter part of the day, and slight protection at night, they will make some growth, which will place them two or three weeks in advance of their natural season of blooming. We get ours into bloom early in August, and they continue to flower until November. Having started

them into good healthy growth, we gradually harden them for exposure about the end of May. Being considered hardy plants, it is natural to suppose that they will bear exposure well. They do not, however, when forced in any way. The young leaves are likely to be disfigured by a chill, and as these leaves remain on the plant all the season, it is important to preserve them. I remember, too, when the thermometer fell to thirty degrees, Fahrenheit, on the last night of August, 1888, all the flowers and buds were destroyed. This has not happened since. When well established, abundance of water should be given. In general, the treatment given Chrysanthemums will answer for them.

These Anemones make good specimens. The handsome vine-shaped foliage and the white or pink saucer-shaped flowers harmonize beautifully. The flowers are borne on stout umbellate cymes, and are nearly two inches in diameter on well-grown plants. By the use of light stakes, such as Privet-canapes make, a good plant in a twelve-inch pot may be spread to three or four feet, and yet be well furnished. They stand the wind and weather well. The variety known as Honorine Joubert is the best white variety, and *Anemone Japonica hybrida* the best pink.

Wellesley, Mass.

T. D. H.

Snowdrops, New and Old.

AS a compensation for the backward season which has retarded some flowers from thirty to sixty days, we have a rather better show of bloom at this time than in seasons when plants flower normally. The earliest Snowdrops are just disappearing as the first buds of Narcissi are showing. Usually we are favored with periods of open weather during the winter, when the early flowers expand. There were no mild intervals during the winter just ending, so that Snowdrops did not open before the end of February, and until lately other winter-flowering plants have had little chance to overcome the obstacle of nightly frosts. The background of snow which is the foil against which these early flowers are usually seen is missed this year.

Snowdrops are now in midseason. The flowers of *Galanthus Elwesii* are about gone, but various other species and varieties are in full flower or not yet open. It is pleasant to note the fine acquisitions to Snowdrops from year to year, for while the older varieties are lovely flowers and not to be discarded, we have now many new kinds, with much larger flowers and in some cases very distinct foliage.

Whenever many gardeners are interested in a certain plant there is a tendency to name varieties on very slight variations, but there are really striking differences in the Snowdrops, which would be more distinctly seen if the foliage was more forward when the flowers are at their best. *Galanthus Cassaba*, which was received from Mr. Whittall last year, has much improved this season, and in respect to size and vigor is among the best Snowdrops in the collection, while inferior to none in beauty. The flowers have sepals over an inch long and rather broad. The petals, marked like those of *G. Elwesii* with green to half their length, have green lines at the apex. The ovaries are a yellowish green. The stems are very thick and upright. The bulbs, which have a long neck, are as big as those of an ordinary *Narcissus*. The leaves are pointed, broad, somewhat *Scilla*-like and glaucous. I believe this is a variety of *G. Elwesii*, and that it was collected near Aidin. A variety sent me by Dammann as *G. robustus* is identical with *G. Cassaba*.

Galanthus Imperati Atkinsi is equally as large and vigorous as *G. Cassaba*, and as the scapes are less stiff it is rather more pleasing in the border. It has the objectionable habit of trying to double its petals, but this objection would not deter one from growing all he could secure of it. Its petals are white, with the exception of green markings on the sinus. This is the most effective Snowdrop in the garden.

Plants of *Galanthus Elwesii* Aidin did not ripen as well as in their native habitat, as they are not as vigorous or prolific as the collected bulbs were last season. Still they prove to be a neat, distinctly marked variety. Some of them still retain their tendency to produce twin-flowered scapes. Last year I discovered one with a most curious twin-flower, which at first glance seemed one of ordinary form. The ovaries of these flowers were flattened at one side where they met, and from each grew only two sepals instead of three, as usual, so that the outward appearance was quite normal. Among these was also a pallid form, of color similar to *G. lutescens*, which is a variety of *G. nivalis*. This has retained its form this year, and as its petals are white with only the faintest suspicion of yellow dots, it is worth a name if it will increase. *G. Ikariæ* Mr. Whittall had collected in the Island of Nicaria. It has wide strap-shaped leaves, light green in color. This proves to be

late, and it is not yet in good form. It flowered well last year with medium-sized flowers, the petals of which, if I remember rightly, had the markings on the sinus connected with the green of the base. It is a very distinct variety.

Galanthus Elwesii unguicularis is a form which has been separated and named, I suppose, from the claw on the spathe. At present it might be matched by some of the types of the collected *G. Elwesii*, among which there is considerable variation. By the way, whoever buys *G. Elwesii* should give the preference to collected bulbs. Cultivated bulbs may sometimes be larger, but the grower will probably retain the finer forms for part of his toll.

Galanthus Ochrospeilus is another of Mr. Whittall's latest finds, and this season flowers for the first time in cultivation. It appears to be a small-flowering kind, oddly marked with a short, green, narrow line on each sinus, and similarly marked at the base. The tube is somewhat constricted at the opening.

A variety from Samos, of last season, does not seem distinct, and differs little from plants from Bithynia, both being forms of *Galanthus Elwesii*. One of the Snowdrops which I most value is Mr. Allen's hybrid, *Charmer*, a flower of fine form, much substance and perfect vigor. Among flowers of great purity the variety of *Nivalis G. Melvelli major* is in the front rank; it is a dwarf kind. Snowdrops unopened, or in the bud stage, are very fascinating, and I enjoy best the long-pointed forms. Of these, *G. Caucasicus* is one of the most pleasing, a happy medium between the narrow *Nivalis* and the broad *Elwesii*. There are numerous other Snowdrops in the garden which I have not had time to study, but it may be well to call attention to one which is especially curious, *G. Scharlockii*, which might be called the horned Snowdrop, as its divided spathes resemble horns in outline. The spathes of Snowdrops are interesting. If a rising Snowdrop is observed it will be noticed that the flower is upright and is enveloped in the spathe, which is mostly a thin transparent membrane. At the proper time this splits at one side usually, and the two edges roll up toward each other till it appears, on a casual glance, to be merely a flat leaf-like appendage, whose top is bent over the pedicel of the flower. In *G. Scharlockii* and a few other kinds the spathe splits in two parts. This Snowdrop has green markings on the outer petals, which are rather blunt. It is not particularly handsome, though well worth growing. It is vigorous and increases rapidly. Most Snowdrops do well in my garden, though they receive no special care or treatment. There are some, however, which will not stay with me. The autumnal flowering ones have disappeared. They seem of too delicate a constitution for the open border, where my scheme of gardening does not embrace any attempt at coddling. *G. plicatus* has not survived with me, though I believe it is not usually a miffy kind. *G. Forsteri* apparently needs a moister richer soil than most kinds, for it still refuses to give me flowers of size and substance.

The Cherry Fruit Mold.

IT is a good thing to grow cherries in abundance, provided the grower harvests his crop, but to have a score or more of large Cherry-trees loaded with fruit left unpicked is a menace to the whole neighborhood. It should be remembered that such fruit left upon the trees, especially if the weather is moist, will develop, literally by the bushel, a fruit mold which is well known from its gray color and soft, powdery feel. This fungus, *Monilia fructigenum*, is not confined to the Cherry-tree, and on this account one can consciously raise complaint against a neighbor who lets the fruit on his Cherry-trees go to decay. The Plum and the Peach are similarly attacked, and the Plum especially is often seriously injured, the whole crop going off just before the time for picking. Suppose the Cherry-trees full of fruit, ripe and decaying. This crop comes before the plums, and the whole atmosphere is charged with the spores of this gray mold of the Cherry. These spores germinate very quickly, the winds carry them in all directions, and the Plum-trees anywhere in the vicinity of such Cherry-trees will receive a full supply of them, so that the fruit cannot escape decay. Spraying will do much to prevent the loss of the plums; but a man will need to be almost constantly in his Plum orchard administering the remedy to counteract the effects of the few large Cherry-trees that were distributing spores throughout the neighborhood.

The Peach in like manner is affected, but coming still later is not quite so apt to be influenced by the crop of *Monilia* on the Cherry-trees as the Plum; but the Peach is attacked somewhat earlier in its stage of development. The surface of the fruit being covered with a down is better able to hold the spores than the smooth surface of the plum, and in that way

the growth may take place while the peach is yet green and hard.

There are many Cherry-trees throughout our middle states that have passed their stage of usefulness and are now doing considerable damage to orchards that otherwise might be profitable. One needs only to drive through the country in almost any direction to find giant Cherry-trees carrying inferior fruit, out of reach of pickers, and comparatively worthless if gathered, which serves as propagation places for one of the worst enemies of the stone fruits. Such trees in many cases could be spared; their owners ought to cut them down. Trees after they have passed their stage of usefulness are not always a source of infection to other trees; but it is manifestly true in the case of the Cherry, which becomes a place for the rapid and abundant propagation of a microscopic enemy to other stone fruits.

Byron D. Halsted.

Yellow-fruited Tomatoes.

THERE are four distinct classes of Tomatoes as regards the color of the fruit; and in this case there is a more than usually intimate association of other qualities with that of color. Of the red tomatoes there are the deep, dark red varieties, like Perfection, Favorite, Ignotum, Optimus and Ponderosa; and a very distinct lighter pinkish colored group of such as Beauty and Dwarf Champion. These are very distinct also as regards texture, flavor and appearance of the flesh.

The yellow varieties are similarly divided into two classes, of which the old-fashioned golden yellow apple-shaped fruit represents the first type. There is almost a metallic lustre to the skins of good specimens of this type. Concomitant characters of this group are thin septæ, tough flesh, large and abundant seeds—a general assemblage of undesirable qualities. The Yellow Trophy seems to fall into this classification here, though, wherever I have seen it it has been very unstable, showing usually several fruits of the next class; and I have often wondered if the seedsmen who sent out the seeds had not selected them from the better strain, and if the trouble was not simply in a reversion of the majority to a type evidently preventient.

The second division of yellow varieties contains strains of later origin, considered either historically or biologically. Golden Queen and Golden Sunrise are the proper representatives of this group, though other names, not well authorized or permanently adopted, have been found to cover similar varieties. The Shah, said to be a sport from Mikado, is also of the same color. These tomatoes are not properly yellow, but are cream-colored, much duller than the other yellows, and not at all metallic in lustre. At the same time they have thick meat, fleshy septæ, small seed cavities, are grainy and tender in texture and pleasantly mild in flavor.

This last group, it seems to me, has not received nearly enough attention, either from amateur or professional horticulturists. The varieties already named, though, perhaps, not so stable as might be desired, have superior table qualities when grown in their perfection; and if this were generally understood, so that the demand for seed might gain some proportions, they would present a fine field for work in seed selection. They are milder in flavor than the best red varieties; and for eating sliced are much finer, according to my taste. Their appearance on the table is also quite as attractive as that of any fruit.

Monsieur G. Alluard, in the last number of *Revue Horticole*, 1895, p. 110, expresses a very high opinion of the yellow varieties. He says: "The best yellow varieties of the tomato make a very appetizing, clear yellow purée, which gives completely the illusion of a fine stew of fruit. The flavor is equal to that of the best red varieties. They are very much better than the red tomatoes for mixing in sauces to which one wishes to give more or less of a tomato flavor. Their color permits this to be easily done, whereas the ordinary tomatoes impart to the sauces a very undesirable red tint. They serve equally well with red tomatoes for making very pretty salads, either in a mixture of alternate slices of the two colors, or put upon separate plates, and garnished with a fresh border of chervil. And lastly, one may use these fine fruits, either separately or in clusters, for garnishing desserts."

It also seems to me that the cream-colored sorts would be superior for canning, though I have not seen them tried. At the canning factories color is a very important quality, the pink varieties, so I am told, being entirely discarded because they do not present an attractive appearance on coming out of the can. Now, I should expect nicely canned specimens of Sunrise to be as handsome as canned peaches when opened. They are somewhat suggestive of peaches when served sliced and

fresh, and are almost as good as that standard of superlative excellence when eaten with sugar and cream.

F. A. Waugh.

Onosma stellulatum.—It was a great pleasure the other day to see in the nurseries of J. W. Manning, at Reading, Massachusetts, a good lot of this beautiful and rare hardy plant, for this is one of the plants that are never forgotten after they are once seen. The Onosmas belong to the Borage family, and all have the characteristic rough foliage; very few are desirable garden-plants, but *O. stellulatum* is an exception, and its drooping heads of bright yellow sweet-scented flowers justify the garden name of Golden Drops, which has been given to it. This same plant is often known as *O. Tauricum*, and the authorities seem now to regard the latter as a fixed yellow-flowered form of *O. stellulatum*, the flowers of which vary from white to various shades of yellow. There is a difficulty often experienced in keeping the plant for any length of time under cultivation, and it is caused in most instances by planting it on a level ground and in soil that is retentive of moisture. A sharp sandy soil, not over rich, and sloping toward the sun, is admirably adapted to its culture. After flowering, the first opportunity should be taken to put in a few cuttings, which should be taken off with a hard base and placed in clear sand, where they will root without trouble, and duplicates can then be had to make good a possible loss. Our losses have invariably occurred during a protracted wet period in dog days. Heavy showers will then bespatter the foliage with soil, and the plants fall an easy prey to damp before the danger is noted; hence the desirability of planting in free soil and the usefulness of placing small stones under the plants to keep the earth cool and protect the foliage. *O. albo-roseum* is an annual species, with which we have never been able to succeed; and we have still another species from seed sent from Asia Minor, but this is not old enough to bloom yet, although it promises to do so this season. Of some seventy species of this genus, the above are about all that are in cultivation now, the rest not being introduced yet.

Lettuce for Forcing.—Every one who tries to keep up a supply of lettuce during the winter months knows the value of a reliable variety. With so many new and old kinds now offered, it is only by experience we can find out which one is most satisfactory when all things are considered. Of several kinds which we tried this winter, Rawson's new Hot House approaches most nearly an ideal Lettuce for forcing. It was grown alongside of some old favorites, such as Boston Market, Tennis Ball and others, but it easily leads all of them. It grows to a large size, hearts quickly and well, has a delicate flavor, and resists damp better than any variety we have ever grown.

Correspondence.

Oranges in Southern Mississippi.

To the Editor of GARDEN AND FOREST:

Sir,—In what may be called ordinary or average seasons oranges ripen well in southern Mississippi, but killing frosts come every few years, so that while oranges are grown here as a luxury they are never considered as a reliable, staple crop. Nevertheless, immunity from cold waves for a few seasons gives every one a sense of security, all precautions against the frost are neglected and then the disaster falls. About this enchanting coast town, in the extreme southern part of the state, up to holiday week, the Orange-trees were loaded with fruit; our Christmas oranges came fresh from a grove in full bearing, and no fruit was ever more beautiful. Then came the sudden drop in temperature, and every orange on the trees was frozen to a solid cake of ice. All the leaves and tender limbs in the groves died, many fine trees were killed outright, and since New Year's there have been three more periods of distinctly freezing weather, to complete the destruction.

The special purpose of my letter, however, is to say that one grove here escaped destruction and is now showing signs of returning growth in every tree but one. The owner is an intelligent Italian, and it may be worth while to give his method of treatment. He says that his father cultivates oranges near Naples, and his practice is the one generally employed there as a safeguard against periods of excessive cold. In autumn he scrapes away the rich top soil from the roots of his trees and allows them to dry, and since he irrigates his grove he at this time withdraws all water. The trees then are at rest, except for the ripening fruit, which seems to be as good as that in

irrigated groves. If freezing temperature comes, these exposed roots freeze with the tree, and yet he claims that their dormant condition and lack of sappiness protects them from harm. As to the correctness of his theory I am not able to pass judgment. I only know that his trees stand with bared roots all winter until there are signs of spring and returning vitality and flowing sap, when he applies his fertilizers and throws back the soil and begins to irrigate. I should add that he does not give his fertilizers all at once, but in moderate amounts every few weeks as the tree needs it. As he waters the trees and fertilizes them as they need feeding, so he keeps down all grass and weeds during the spring and early summer, so that they cannot rob the grove and prevent the trees from securing the full benefit of the food. The one tree lost stood in the rear of his house where the waste water from the kitchen reached its roots. This tree was in growing condition in the autumn and the frost killed it. My attention was called to the fact that after the first frost every Orange-tree in his grove cast its leaves, which their proprietor noted as a sign of life, for trees struck by lightning or otherwise deadened hold their dead foliage apparently without the power to cast it off.

Pass Christian, Miss.

A Large Grapevine.

To the Editor of GARDEN AND FOREST:

Sir,—Some time ago GARDEN AND FOREST suggested that it would be of interest if observers in different sections of the country should make a note of the size of the Grapevines in their several neighborhoods. The largest one I have ever seen is growing at Rose Dhu plantation, on the May River, South Carolina. This vine, supposed to be *Vitis aestivalis*, grows on the edge of a bluff three or four feet high, at the base of a large Live Oak, and measures, at three feet from the ground, forty-eight inches in girth, and at one foot from the ground fifty-four inches in girth; this lowest portion of the stem, however, is protuberant and nodose. One of the large cable-like limbs extends out near the adjacent marsh, then dips down into the mud, in which it is somewhat buried, doubtless deriving some sustenance and growth from the salt water which laves it at every tide. Other portions of the vine clamber out and clasp the large limbs of the Oak in innumerable folds of cordage, covering the Oak from top to bottom, then extending out to and covering two other Live Oaks, one to the right and the other to the left of the central tree, the distance between which measures at least twenty paces—thus making the finest picture of a true "Forest Lao-coon" which I ever saw on the Carolina coast.

Exhibitions.

Spring Flower Show in Boston.

THE exhibition of the Massachusetts Horticultural Society, held here last week was as good, at least, as any of its predecessors, and many thought it better than usual, owing to the fact that the mild weather which prevailed early in the week enabled the growers to transport their plants in fine condition. The most striking feature of the show was the Orchid exhibition, and probably its excellence was partially due to the premiums offered for the tasteful arrangement of these flowers with other plants. The difficulties of arranging a table of Orchids for effect are well known, and yet Mr. William Robinson, gardener to Mrs. F. L. Ames, did his work with excellent taste and skill. He had abundance of material to begin with, and the foliage of various Adiantums, and small Palms like *Cocos Weddelliana*, were plentifully used to bring out the colors of the flowers and give a finish to the groups. In the collection there were very many rare Orchids, and some unique ones, particularly the exquisite forms of *Odontoglossum crispum*, with well-marked flowers on long sprays. The wonderful pea-green and maroon-striped *Cypripedium Rothschildianum*, with three spikes, each bearing three flowers, was probably the most noteworthy single plant on exhibition, and it would be hard to find a better example of high cultivation. When this *Cypripedium* is seen in such admirable form as this there is little wonder that it is so much admired. A plant of *Miltonia Bleui splendens* with its two spikes, each bearing flowers four inches across, was another striking specimen, and it recalled the beautiful pictures of the plant published in GARDEN AND FOREST, vol. v. The second prize group of Orchids was from the gardens of Mr. John L. Gardner, and in the collection of Mrs. Durant, of Wellesley, was a remarkable specimen of *Dendrobium nobile*, in the cultivation

of which the gardener of the establishment, Mr. Butler, is a recognized master. This plant was grown in a fourteen-inch pan; it was nearly three feet in diameter and carried between nine hundred and a thousand flowers. It was an excellent object-lesson in the way of pruning *Dendrobiums*, since all the growths that had flowered the previous year had been cut out, leaving only those of the present year with few of last year's pseudo-bulbs, nearly all of which were bearing. Mr. Butler showed a plant similar to this two or three weeks ago, and these are two, we believe, of several that he has grown on from small plants.

Of course, there was a large display of forced bulbous plants, the best being those shown by Mr. Kenneth Finlayson, gardener of Dr. Weld, and the Bussey Institute. It is a pity that there was no full collection of *Narcissi*. Our gardens show no more attractive flowers than these, and there are numerous species and varieties, with new forms of distinct merit, appearing every year. The best *Tulips* were *Prince of Orange*, *Thomas Moore*, *Duchess of Parma*, *Kaiser Kroon*, and some of the best *Hyacinths* were *Queen of the Blues*, *Lord Derby*, *King of the Blues*, *Gigantea*, *Macaulay* and *Leviathan*. *Cyclamens* are always well shown at this exhibition, and the contest for first honors between well-known exhibitors has always been close. This year a new competitor appeared in Mr. John Barr, gardener to Mrs. B. P. Cheney, of Dover. He received the prize for the best ten plants, which, although they were not larger than those of his closest competitor, seemed to excel in color, size of flowers and neatness of habit. The *Cinerarias* made a fine display, although the efforts in the way of recent improvements with different strains have been mostly directed to the increased size of the flowers, and, to make a gain in this direction, compactness of habit has been somewhat sacrificed. These large-flowered varieties mostly bloom early, and before the plants have made a good foundation of growth, so that the relatively small-flowered plants make the best specimens. The first honors in this class went to Mr. James Carthy, of Fairhaven, who showed some magnificent specimens, although the individual flowers were somewhat lacking in size.

The forced shrubs exhibited by the Bussey Institute included *Forsythias*, *Lilacs*, *Philadelphuses*, *Spiraea Van Houttei*, several *Ericas* and *Ghent Azaleas*. The new white *Snapdragon* which Mrs. Wood, of West Newton, exhibited at the meeting of the Carnation Society a few weeks ago, was shown again; and since it has been proved that this showy biennial can be forced, it is likely to be extensively grown for decoration wherever bold displays are required.

Among the cut Roses were splendid flowers of *Paul Neyron*, *Magna Charta*, *General Jacqueminot* and other Hybrid Perpetuals, shown by David Nevins, Esq., of Framingham, Massachusetts. Mr. A. Mackay, his gardener, can be congratulated on having grown as fine Roses of this class as were ever seen in a Boston exhibition. The flowers of *Catherine Mermet*, shown by Mr. Meade, of Dorchester, were exceedingly well done, and gave a new proof that this remarkable Rose was still holding, as it has done for almost a century, a leading place among the pink Tea Roses. Its one defect, that of a loss of color on maturing, does not appear in *Bridesmaid*, which is a sport from it, and some magnificent blooms of this flower were exhibited by Mr. Frank Pierson, of Tarrytown, New York, while some flowers of another sport from *Catherine Mermet*, *The Bride*, were shown in first-rate condition by Mr. Elliot, of Brighton, Massachusetts. It is to be observed that this variety has also the defect of turning yellowish as it comes to maturity, which accounts for the fact that is yielding to some extent to the *Kaiserin Augusta Victoria*. This last Rose, however, is a hybrid Tea, and, therefore, can hardly compete with *The Bride* for all-the-year blooming.

Mr. Nicholson, of Framingham, carried off the honors for a display of Carnations, while *Storm King*, *Uncle John* and *Stuart*, all of which failed, to some extent, to meet the expectations of their friends at the meeting of the Carnation Society, were here shown in remarkably fine condition by the Cottage Gardens, Long Island.

It was a pleasure to see such a fine display of hard-wooded plants. Dr. Weld's specimen of *Acacia Drummondii*, some seven feet high, with its long pendent racemes of bright yellow flowers, made a charming picture. In the same collection was the Heath-like *Diosma capitata*, with its heads of lavender-blue flowers; *Eriostomum nerifolia*, with its star-shaped bluish white flowers; the elegant *Boronia heterophylla*, with globular pink flowers, as well as *Correae* and others. Two small plants of *Boronia megastigma*, from the gardens of Mr. John L. Gardner, filled the hall with their perfume, and from the same collection there was a magnificent standard plant of *Acacia*

pubescens, with a head six feet across, with drooping branches all tasseled with golden flowers. A young Orange-tree, which contained at once blossoms, green and ripe fruit, from N. T. Kidder's collection, was also very attractive, and *Baurea ruboides*, a handsome little shrub with pendent, pinkish, saucer-shaped flowers, from New Zealand, was new to most visitors.

Boston.

S.

Notes.

One of the very best, if not the best, of Strawberries for forcing is the old but somewhat scarce variety *Triomphe de Gand*. It will fruit abundantly in four-inch pots and it is always a sure cropper under glass.

For a week or two past the sidewalk fruit-stands have been decorated with branches of *Kalmia latifolia*, its glossy green leaves being very effective in setting off the colors of oranges, bananas and apples. Leafy twigs of Wild Cherry are largely used during the summer for the same purpose, but these Laurel leaves have only lately come into such general use. The supply comes from the coast counties of New Jersey.

A series of excellent photographs of wild flowers, made by Mr. Cornelius Van Brunt, of this city, and colored by Mrs. Van Brunt, will be used as lantern slides to illustrate a lecture on Wild Flowers in and about New York City, which Mr. Van Brunt will deliver at Hardmann Hall, on Fifth Avenue and Nineteenth Street, on Wednesday evening, April 3d. The lecture has been already given before the Torrey Botanical Society, of this city, when it was highly commended, and it is to be repeated by request.

According to a writer in the *Youth's Companion*, the largest forest in the world is in Siberia, stretching continuously from the plain of the Obi River, on the west, to the valley of the Indigirka, on the east, and embracing the great plains or river valleys of the Yenesei, Olenek, Lena and Yana, the vast belt averaging more than one thousand miles in breadth from north to south, and some three thousand miles long. The trees are mostly coniferous, and they cover thousands of square miles, whose central regions no human being has ever visited. Long-stemmed conifers, rising to a height of one hundred and fifty feet or more, stand close together, and their dense lofty tops exclude the pale arctic sunshine, and the straight trunks, all looking exactly alike, bewilder the eye in the obscurity, so that all sense of direction is lost. Even the most experienced trappers dare not venture into these forests without blazing the trees constantly with hatchets as they walk forward, for a hunter lost there rarely finds his way out, but perishes from starvation or cold.

Mr. H. G. Hubbard, the entomologist of the Department of Agriculture, writes that the cold weather which desolated the gardens and Orange-groves of Florida, killed unnumbered millions of injurious insects. All cockroaches in sight, and even those in houses, unless they were exceptionally well protected, were killed. The young scale insects which had not passed their second molt were killed, although many eggs survive, and some adults of both sexes. The nitidulid beetles in decaying fruit were also killed, small gnats in flowers were frozen, and not a living colony of plant-lice is to be seen on any Orange or other tree. No living specimen of the destructive white fly, *Aleyrodes Citri*, was found, and as the eggs are laid on the leaves, every one of which will drop before the new growth appears, the cold wave would have almost exterminated this pest but for the fact that, besides the Orange-tree, it also infests the Cape Jessamine, and as the leaves of these plants have not all fallen, Mr. Hubbard is advising the orange-growers to cut down their Jessamines and burn them. Since the breeding of injurious insects has been suspended now for some weeks an excellent opportunity has been offered to clear the trees of scale with comparatively mild insecticides. On the other hand, the trees have been so enfeebled by the cold that they will be an easier prey to injurious insects than they were before.

Dr. E. F. Franceschi writes in the Santa Barbara *Press* that the Norfolk Island Pine, *Araucaria excelsa*, thrives remarkably well in that town, some of the older specimens being already more than one hundred feet high; most of them are now bearing cones which appear to ripen perfect seeds, so that in some places there are young plants growing from self-sown seeds—that is, the tree has become practically naturalized. A Cookii, from New Caledonia, also bears cones there, while

specimens of *A. Bidwelli*, *A. Cunninghamii*, *A. Brasiliensis* and *A. imbricata* are doing well, although none of them have flowered as yet. The most remarkable exotic conifer is, perhaps, the splendid specimen of *Dammara*, which was planted more than twenty years ago on what are now the grounds of Mr. E. H. Sawyer, at Montecito. The tree has never flowered, and until it does it can hardly be identified. Dr. Franceschi hardly thinks it is the true Kauri Pine, from New Zealand, *Dammara australis*, and it has been doubtfully referred to *D. robusta*, from Queensland, while others are inclined to consider it *D. orientalis*, from Java. An apparently different species of *Dammara* with broader leaves is to be seen in *Carpinteria*. Of true exotic Pines there is a specimen of *Pinus maritima*, from the Mediterranean basin, in Santa Barbara, which is now twenty-five years old, and some fine Stone Pines, *Pinus Pinea*. The pyramidal form of the Italian Cypress, *Cupressus sempervirens*, has been much planted, and there are splendid specimens of the Weeping Cypress, *C. funebris*, from China. *Cedrus Deodara*, *C. Libani*, *Cryptomeria Japonica*, *C. elegans*, *Sciadopitys verticillata* and several other Asiatic conifers have been planted recently, and all do well. Dr. Franceschi thinks there is no other place in the United States, and, perhaps, none in the world, where such a rich and instructive pinetum could be planted, since the conifers of widely different climates seem to thrive in Santa Barbara equally well.

Every year increases the demand for grape-fruit, as people will insist upon calling the pomelo, and those who have learned to appreciate its value as a breakfast fruit in winter feel that they have something like a personal grievance when they are deprived of it. It is an expensive luxury now, however, since almost the entire supply came from Florida, and, except the limited number of boxes picked before the holidays, the entire crop was destroyed by the killing frost at the beginning of the year. Small quantities of this fruit were brought from the West Indies a few years ago, but it could hardly be given away, and no attempt has been made to cultivate it systematically on any extended scale in those islands. A week ago a few barrels were brought in from Jamaica, and they sold at auction at \$24.00 a barrel, the highest price ever realized for this fruit in New York. At retail a good pomelo costs half a dollar. As we have stated before, every orange-growing region of the world was laid under contribution as soon as the disaster to the Florida crop was known, and, therefore, the supply of this fruit is still overabundant, and oranges from Sicily can be bought here for less money than they bring in the groves where they were produced. Probably a hundred thousand dollars have been lost by the large dealers in this fruit in this city within a few weeks past. The supply of California Navel oranges, however, is now running low, and prices for fine fruit are growing more firm. The cold weather has retarded the growth of pineapples, so that the season is uncommonly late. Last week fifty-six barrels came into this port, and a year ago they were arriving at the rate of three thousand barrels a week. Of domestic fruits, pears are no longer quoted in the market reports, although in the fancy-fruit stores some of the best late winter varieties, like P. Barry, one of the long-keeping Fox seedlings, can be had at seventy-five cents a dozen. The apple supply is, of course, falling off. Ever since the middle of September this fruit has been coming into New York at the rate of about twenty thousand barrels a week. Last week, however, only six thousand arrived. Varieties, like Ben Davis, Northern Spy and Baldwins of good quality, bring at wholesale \$4.50 a barrel, while choice Spitzbergs, Winesaps and Greenings cost \$6.00. Strawberries, from Florida, have fallen to fifty cents a quart, while choice berries from farther north can only be afforded by wealthy buyers. Asparagus, from Charleston, has been in full supply, and the price has dropped to \$1.00 a bunch. Green peas sell at \$5.50 a crate. The finest salad plants in the market now are dandelion and chicory, from New Jersey, and Romaine lettuce, for which last Bermuda gardens seem to have a monopoly in this market.

Mr. William S. Kimball, of Rochester, died on the 26th of March, after a brief illness, at Virginia Beach, where he was spending the winter. Mr. Kimball has long been known as one of the most liberal patrons of horticulture in America. In Orchids, especially, he took an enthusiastic interest and was known to all dealers in rare plants of this class. He bought with intelligence, and being a man of abundant means he had amassed a collection which in its completeness and in the value of its individual plants had few rivals in the world.

A Notable Park Project in New Jersey.

BEFORE this article is published the people of Essex County, New Jersey, will have decided at the polls whether they will approve of the law passed by the last Legislature of the state, authorizing the expenditure of \$2,500,000 for public parks, and at this writing there seems to be practically no opposition to the measure. The natural way in which this public sentiment in favor of parks has been developing for the past twenty years, until it has at last blossomed out into this actual and practical effort, is a most auspicious beginning for the enterprise, and the absence, so far, of any suspicion of self-seeking in the enterprise by any clique or any interest, is an additional encouragement to all its well-wishers. The fact that Newark city is not alone interested, but that the entire cluster of cities and towns within the large and populous county are to be united in the project, establishes a novel precedent in the history of public parks, and since Essex County has little debt the tax will be no burden, while the valuations of property facing the new parks and parkways will be sure to advance sufficiently to more than pay for the improvement.

It is fortunate that the movement has assumed this comprehensive form and that active measures are to begin at once, for not only the city of Newark, but the Oranges, Montclair and other growing towns of that region are spreading out over the country at such a pace that in a short time there will be no rural scenery left for popular recreation. Even now, although the townspeople can ride out to hills on various trolley lines for a single fare, they have little opportunity to come into contact with unspoiled nature, for their walks must be confined to the country roads. Of course, they are shut out from the woods and fields owned by private persons, and, on the other hand, the suburban residents are beginning to complain of annoyances by these throngs, especially on a bright Sunday. It is time, therefore, that some of the beautiful scenery should be set apart and devoted to public use forever. The rolling country in the northern part of the county, the equally beautiful region of wooded hills on its southern border, to the east and west of Short Hills, not to speak of the magnificent slopes of the Orange Mountain,

with its unrivaled prospect, including the harbor of New York, offer park land of the most varied and interesting character, and all accessible to a population now counted by hundreds of thousands, and increasing with marvelous rapidity.

The new Park bill authorizes the expenditure of two and a half million dollars, under the administration of five commissioners to be named by the Justice of the Supreme Court of that circuit, and they have full power to condemn land, to receive gifts, to take charge of the necessary roadways, to provide a system of maintenance, to assume control of existing parks, and, in short, to do all that is necessary in a park system in the way of construction and management. There are considerable spaces of land already held by the cities and towns which will be included in this park system, comprising old reservoir sites, lands taken for taxes, ancient commons, gores of land at intersecting highways, and the money authorized will suffice to secure land for three or four large parks in different parts of the county—one, perhaps, on the Orange Mountain, one near the flat Newark meadows, where there is a large factory population, one on the rolling lands west of the Passaic about Belleville and Franklin, and another still to the south, perhaps in the vicinity of Waverly, where the land is also rolling and where there is some water. In addition to the greater park areas and the smaller parcels of lands already possessed, the funds will suffice to secure connecting ways, playgrounds and all the open spaces actually needed, and, besides this, it is believed that many public-spirited citizens will make donations of land where it can be used to round out and complete the park system.

If we were asked to make a suggestion to the commissioners whom Judge Depue is to appoint, we should say that since these parks are situated in different parts of the county, and each one is surrounded by a population with distinct characteristics, the sites should be chosen not only to meet special needs in each case, but they ought to be selected as component parts of one comprehensive plan, so that each one shall be a complement to all the rest and furnish attractive features not offered by the others. Besides this, the usefulness of these parks would be greatly enhanced if broad roadways could be secured to connect them with each other and with what are to-day different cities, but which will be within a few decades different sections of one great city. In this way the practical park area will be largely increased, and the property along these parkways will be greatly enhanced in value, for the most inviting place of residence in the county will be found along their lines.

And this leads to another suggestion, which is, after all, the one of prime importance. Any park will lose half its value, and often more than half its value, unless it is prepared by a skilled designer. No man would think of erecting a building worth two millions and a half without employing the best architect who could be secured, and the parks of Essex County will cost much more than that amount before they are completed. Therefore, a skilled landscape-architect—an artist who has demonstrated his ability to cope with all the problems presented in a work of such magnitude as this—is essential. Moreover, the time to call him into consultation is before the ground is bought. It is a well-known fact that has been proved over and over again in the history of parks in all the great cities of the world, that if the designer is called in after the land is bought, he finds certain approaches and modifications of boundaries necessary, and the cost of what is needed afterwards to finish out the whole into a perfect picture is often nearly as much as the cost of the original land, because of the suddenly enhanced value of the property adjoining the site. After Central Park was bought and the plan was made, it took nearly half a million dollars to buy the small square at Fifth Avenue and Fifty-ninth Street, known as the Plaza, which was needed as a vestibule to give the great pleasure-ground some dignity of approach and entrance. The proper way, therefore, is to invite the trained park maker

to advise in the selection of the ground and in fixing its boundaries. It is very plain that these boundaries can be much more intelligently laid when something like a general scheme has been decided upon by the designer. It will cost less money, it will be a safeguard against expensive and ruinous mistakes, and it will enable the city to acquire priceless possessions that otherwise will be lost forever.

Very rarely has a community had so splendid an opportunity for a series of pleasure-grounds. Their design should be entrusted to no one who does not stand in the very front rank of his profession. Let us hope that Essex County will prove herself equal to the occasion.

A California Brook Side.

CALIFORNIA has such a wide variety of soils and climates that its experiment stations are properly distributed about the state, and when the system is complete, one who visits the main outlying stations in succession will traverse a road which varies in altitude from the sea-level to 8,000 feet above it, and make a journey of 3,000 miles before he finishes the circuit. The Chico Forestry Station is in Butte County, in the upper Sacramento valley, and beautifully situated south of Chico Creek. The work there has already been described by our correspondent, Mr. Shinn, and that much of the land hereabout is favorable to tree growth is evidenced by the fact that the famous Hooker Oak, on the grounds of General Bidwell, which was illustrated and described in *GARDEN AND FOREST*, vol. iii., page 606, is only a mile from the station. The illustration on page 145, from a photograph sent by Mr. Shinn, is given to show a characteristic bit of scenery in this neighborhood, the view being taken from a point on Chico Creek. Except in the higher mountains of California, there is usually a less shrubby undergrowth along the brooks than there is in the eastern states, and they are, therefore, less attractive. What strikes the eastern visitor most is the fact that the Alders which often line their banks are large trees instead of shrubs, as they are here, and that our low-growing Willows are also replaced by trees of considerable size. The principal trees in this picture are the Plane-trees or Sycamores, *Platanus racemosa*, which the early botanical explorers confounded with our Sycamore, *Platanus occidentalis*, until it was distinguished by Nuttall in 1835. The tree sometimes reaches one hundred and twenty feet in height, with a trunk as much as nine feet in diameter above its broad tapering base, often free of branches for half its height, but more frequently dividing into several secondary stems near the ground, reclining or prostrate for twenty or thirty feet after they separate. The branches of these trees are long, spreading and contorted, making an open round-topped, though irregular, head. It is found in the valleys and along the banks of streams, and is one of the noblest deciduous-leaved trees on the Pacific coast.

Scotch Pine in the West.

OF the various conifers easily obtainable in the commercial nurseries, the Scotch Pine, *Pinus sylvestris*, has succeeded over a wider area than any other, with the exception of the Red Cedar. It seems to do equally well in Dakota and Kansas, and one of the best wind-breaks that I have seen is made of Scotch and Austrian Pines at Ainsworth, Nebraska, near the one-hundredth meridian, on high dry prairie. These Pines were two years old when planted, nine years ago, and they are now from twelve to eighteen feet high, and average eighteen inches in circumference two feet from the ground. Armstrong is ten miles south of the Niobrara River, and the soil is the usual clay loam of the plains. Notwithstanding the unprecedented drought of last year these Pines made a fair growth and were stocky and vigorous when examined in October.

In the spring of 1888, five hundred Scotch Pines, from

eight to fifteen inches high, were received at the South Dakota Agricultural College. The trees were set in nursery rows, cultivated and mulched, and eighty-six per cent. of them grew, the average growth for the season being four inches. The following spring these trees were set in mixed plantation with Silver Maple, Birch and Cottonwood. The transplanting was carefully done, but a poor stand resulted. In October, 1894, the Pines averaged four feet high, the tallest being eight feet nine inches. The average growth for the past dry year was eleven inches. This illustrates very well the action of the Scotch Pine throughout the west. As with most other conifers, it is difficult for it to become established, but once a stand is secured there is no further difficulty.

There are a number of fine Scotch Pines at Arbor Lodge, the home of the Secretary of Agriculture at Nebraska City, Nebraska. One of these measured thirty-two feet in height and five feet in girth, breast-high. Standing in the open it had branched freely near the ground, making a broad spreading crown. At Franklin, in Nebraska, the south tier of counties and near the ninety-ninth meridian west, the Scotch Pine is vigorous, and trees ten years from the seed measured twelve feet high. A tree that had been planted in prairie sod when two feet high, ten years ago, measured fifteen and one-half feet high. It is impossible to imagine a condition of greater drought than prevailed at Franklin last year. When seen in October the land showed no trace of moisture, even in the fields.

Scotch Pine was tried in an experimental planting in the Sand Hills of central Nebraska, but only a few trees lived, but these did not equal the Banksian Pine in growth. The soil of the region is nearly pure sand, raised in high ridges and almost devoid of vegetation, only a few species of the hardiest plants growing on it.

Fine young specimens of Scotch Pine were seen in the suburbs of Denver, where all trees are irrigated. In the rich sandy loam of the Smoky Hill River, at Salina, Kansas, the Scotch Pine flourishes, many large trees growing in the lawns of that pretty prairie town. At Ogallah, on the high dry plains of western Kansas, one Scotch Pine, planted several years ago in the unbroken prairie sod, is growing slowly, but is evidently in perfect health. At the Kansas Agricultural College, Manhattan, the Scotch Pine has not succeeded as well as the Austrian Pine in close plantation. It has grown taller, but does not look as vigorous. However, the comparison is hardly fair, as there are many more Austrian than Scotch Pines in the plat, and the latter are more closely planted.

It is safe to assume that, once the trees have survived their first year in their prairie home, no conifer that has thus far been largely tested gives better results in the west than the Scotch Pine.

Washington, D. C.

Charles A. Keffer.

Exhaustion of Soil by Trees.

A CORRESPONDENT of *The Country Gentleman* writes as to the comparative exhausting power of different kinds of forest-trees upon the soils where they have grown. He had heard that the Pine-barrens are so called because Pine woods made land barren and that certain native species are poison to land. The letter was referred to Mr. B. E. Fernow, chief of the Forestry Division of the Department of Agriculture, and we quote the main points in his reply :

As far as exhaustion of minerals from the soil is concerned, no fear need be entertained, since forest-trees require only the smallest quantity of the commoner kinds of minerals from the soil, and in addition they return the bulk of these to the soil in a more soluble form by the fall of leaves and twigs; hence they improve the top soil, as is well known. The foliage of some trees decomposes more readily than that of others, and forming a humus of more or less desirable composition, this beneficial effect varies with the species; thus, while the conifers, especially Larch and Spruce, as well as the Beech, are among the greatest improvers of soils, the humus from Catalpas, Black Locust, etc., is of little use, while the foliage of the

Oaks decays but slowly, and hence does less for the improvement of the soil. But the saying that "Red Oak and Black Walnut poison the soil" is probably an overstatement—at least, we have no knowledge that this is really so or any reason to believe it; they are simply less useful in making humus.

Of much more moment to tree-life than the minerals, is the water of the soil, and in respect to the amount of water transpired, trees differ very widely, so that, in general, deciduous-leaved trees may transpire six times as much as coniferous trees. The Pines especially are moderate users of water. These latter are satisfied with such small amounts, that they can occupy the dry sands of the Pine-barrens to the exclusion of other species.

The deterioration of soil under given trees, then, depends upon the rapid exhaustion of the soil moisture. This exhaustion is, however, much less due to the transpiration by the trees themselves, than to the surface evaporation, and this again is dependent upon the amount of shade which the trees exert. Under a dense growth of the shady Beech, Hemlock, Spruce, Sugar Maple, etc., no exhaustion of moisture takes place, while under the light-foliaged Birch or Oak, especially in later life when the crowns become thinned out, the sun reaches the soil readily and much water is evaporated. In addition, if these trees stand alone in a field, the raindrops readily fall through the foliage upon the soil and compact it; thus much less water can percolate and the evaporation from the compacted soil is increased, as every farmer will understand who cultivates his crop in order to reduce evaporation.

As far as influence upon neighboring crops is concerned, trees exert a deleterious influence upon the immediately adjoining portions either by their shade—and some species are shadier than others, hence a difference in degree of effect—or by their competition for moisture. Some kinds, like Cottonwoods, Willows and Elms, require not only more water than others, but their root systems are capable of rapid and enormous extension in search of water, so that their influence is far-reaching. Grape-vines are of the same nature, so that it is almost useless to cultivate in the neighborhood of a vineyard, unless the soil contains a superabundance of moisture.

The taproot trees are less injurious, because they supply themselves from greater depths, while the shallow-rooted ones, like Black Locust, Beech, Spruce, etc., compete on the same level with the annual crops.

The Kerosene Attachment for Spraying Pumps.

IN a brief report of a meeting of the Association of Economic Entomologists, in the last volume of GARDEN AND FOREST, page 480, mention is made of the implement devised by me, by means of which kerosene is mixed with water at the instant it passes through a spraying nozzle, so as to obviate the need of making an emulsion previously. The machine was arranged so that the piston draws on both the water and the kerosene supply at once and mingles the two fluids in correct proportions. Mr. Marlatt, of the Department of Agriculture, stated that the practical working of the machine with him had rendered any application of the oil dangerous to plants, since it was impossible to foretell the percentage of each substance used. In my own work with this attachment every trial but one was satisfactory so far as the destruction of the insects was concerned, nor was there any case where the foliage was injured except in one instance where fifteen per cent. of kerosene was purposely used on the Raspberry. Mr. Marlatt's work, however, has led me to make a more careful study of the apparatus, and I offer here a report of my experiments:

I find that there are two reasons why the apparatus I have used is liable to throw variable quantities of kerosene. The varying level of the two liquids is one, and the fact that the air-chambers of the pump is located directly above the discharge-pipe is another. The first is liable to cause inequality by varying the heights to which the two liquids are lifted; the second by permitting the kerosene to accumulate in the portion of the pump-chamber located above the discharge-pipe,

and this accumulation is forced down and out whenever the pressure in the chamber is relaxed. Both of these inequalities are, however, capable of easy remedy by changing the form of the reservoir to hold the liquids, and by altering the relative position of the air-chamber and discharge-pipe of the pump.

For the water reservoir, I used a five-gallon tin can, to which were attached three legs near the top (as shown in figure 21), on which it can stand securely in an inverted position. Then a tin basin was attached to these legs at such a position that when the can is inverted the bottom of the basin hangs an inch and a half beneath the mouth of the can. In the drawing (see fig. 21) the front side of this basin is represented as being cut away to show the mouth of the can. In the centre of the bottom of this basin is soldered a neck to which a screw-cap is fitted. Through this neck the tube of a funnel can be passed, so that it will enter the mouth of the can for filling.

Near the top of this can (or near the bottom when in its inverted position) is soldered a staple of heavy tin, to which is attached, by means of a hook, a one-gallon can, with a basin suspended beneath its mouth, as in the larger can, the smaller can being used for kerosene. The kerosene can is hung at such a point that its mouth is on a level with that of the larger can. This arrangement maintains the two liquids at practically uniform levels. The suction pipes are placed in the basins, and the liquids are supplied from the cans as fast as they are drawn out.

The change made in the pump will readily appear in fig. 22, which is intended to show the air-chamber of the Climax pump. The discharge was originally at A, and the part of the chamber above this orifice answered as the air-chamber. I attached the discharge at B, and extemporized an air chamber at A by uniting sections and fittings of gas-pipe. With this arrangement there is no opportunity for the kerosene to accumulate by separation above the discharge-pipe. Should a very little accumulate in the air-chamber, it is not likely to be forced back until after the pumping has ceased.

With this arrangement of the pump and the reservoirs I have secured excellent duplicates in the proportions of kerosene distributed at different times. In these trials a Nixon nozzle, with a fine orifice diaphragm and medium gauze, was used, and a second diaphragm with a fine orifice was added at the union of the hose with the pump, which I find increases the intimacy of the mixture. The stream was permitted to flow for a moment after starting the pump, after which it was directed into graduated glass cylinders of 500 cc. capacity, and three cylinders were filled in each trial, sometimes in immediate succession, and sometimes the spray was directed elsewhere for a time after filling one before it was turned into the next. After the cylinders were filled they were permitted to stand for a few hours for the kerosene to separate from the water. The test was repeated on several different days, and with the cock in the kerosene tube set to throw quantities of kerosene varying from two to twenty per cent. For some unexplained reason, the proportion of kerosene would increase a little until a few strokes had been made on the pump, but after this it remained almost entirely constant, rarely varying more than two or three tenths of one per cent. in the different cylinders in the same trial.

These results are certainly sufficient to show that the difficulties experienced by Mr. Marlatt were due to defective mechanical arrangement, and not to a defective principle.

The cans used in my experiments are not expensive, and if well cared for when not in use should last many years. With a properly constructed pump, and with the exercise of as much care as is necessary in the use of the Bordeaux or Paris green mixture, the apparatus used in my former experiments will give satisfactory results, so far as destroying insects without harm to foliage is concerned. Still I shall hereafter employ the cans, since they insure a uniform distribution of the kerosene. The saving in the cost of the soap over using the kerosene-soap emulsion will soon amount to the cost of the cans, and no one who has tried the mechanical method of combining kerosene and water will dispute the great saving of labor effected by it, as compared with the kerosene emulsion.

Experiment Station, Madison, Wis.

Foreign Correspondence.

London Letter.

Cœlogyne Micholitzii.—A large number of newly imported plants thus named were sold here by auction this week at the instance of Messrs. F. Sander & Co., with the descriptive statement that this *Cœlogyne* was discovered by, and named after their collector, Mr. W. Micholitz, who writes that he has one flower-stalk twenty-seven inches long, which has borne seventeen flowers. The dried flowers are described as of large size, pure white and of great substance. In pseudo-bulb, foliage and flower-scape this plant bears a close resemblance to *C. barbata*, but it appears to be larger in all its parts. It belongs to the section of the genus named *Proliferae* by Dr. Lindley, by reason of "a second scaly sheath being often produced beyond the first series of flowers, and out of that sheath arises a second series of flowers." The plants were in good health, and good pieces brought five guineas each.

Dendrobium Apollo is the largest and handsomest of all the hybrids bred from *D. nobile*. Its parents were *D. Ainsworthii* *splendidum* and *D. nobile pulcherrimum*, and it was raised by Messrs. Cypher & Son, of Cheltenham, perhaps the most successful growers of *Dendrobiums* in England. A plant of it in flower was exhibited by them last week. It has the habit of a strong *D. nobile*, and flowers like those of *D. Ainsworthii*, but the segments are broader and longer, the spread of the flower being fully three inches, while the color is like *D. Ainsworthii*, but darker in the labellum. This is a plant to be looked after, a truly noble Orchid. No doubt, Messrs. Cypher intend to propagate it as rapidly as possible, and as all the *D. nobile* hybrids are easy to cultivate, and may be propagated from pieces of pseudo-bulb, we ought not to have to wait long for an adequate supply of the well-named *D. Apollo*.

Masdevallia Melanoxantha.—This is an interesting species, of which an example in flower was exhibited last week by Messrs. F. Sander & Co. It is the true plant as described by Reichenbach some twenty years ago, and not *Masdevallia Mooreana*, which, however, often does duty for it in gardens, although the two are widely different. A figure of the latter may be seen in the *Botanical Magazine*, t. 7015, and one of *M. melanoxantha*, the first published, is given in *The Gardeners' Chronicle* for this week (page 359). It has fleshy spoon-shaped leaves, like those of *M. Harryana*, and erect single-flowered scapes, the flowers being remarkable for their flat black-purple lower sepals, which are united almost to the apex, forming a bilobed body an inch wide and an inch and a half long. The upper sepal is rigid, narrow, at right angles to the lower, and concave at the base. The labellum is hairy. It is quite distinct from all other cultivated *Masdevallias*, and in attractiveness would rank among the second-rate species.

Phaius Amabilis is a worthy companion to *P. Cooksoni*; indeed, the two might with some reason be called forms of one. The principal difference is in color, the former having flowers of a pale pink color and a dull crimson lip covered with reticulating lines of greenish rose, the outside color being coppery red. It was raised by Messrs. F. Sander & Co. from *P. grandifolius* and *P. tuberculosus*, and was awarded a first-class certificate two years ago. There is a good number of plants of it in the St. Albans nurseries, from whence a group of flowering examples were shown last week along with fine flowering specimens of *P. Cooksoni* and *P. Marthiae*. These hybrids are specially valuable, as they have inherited much of the floral beauty of *P. tuberculosus*, and, at the same time, are as robust in growth and as easy to cultivate as *P. grandifolius*, which in tropical countries is used as a bedding-plant. I have seen good specimens of it grown in river mud, and magnificent plants of it have been grown in the same soil as and treated with garden Crotons.

Maxillaria Sanguinea.—This species was first introduced about four years ago from Chiriqui, and it has since flowered at Kew and elsewhere. A description of it was lately

published in the *Kew Bulletin*, and Messrs. F. Sander exhibited it in flower last week. It belongs to the same group as *Maxillaria tenuifolia*, having a slender rhizome, small ovate pseudo-bulbs an inch long, and grassy dark green leaves about a foot long. Flowers singly on short erect peduncles, an inch across, the sepals and petals brown, the lip crimson, with a few small dark brown spots about the crest and a pale-colored margin. It belongs to the modest wee things among cultivated Orchids, and is quite worth including in good collections.

Gladiolus trichonemifolius is a pretty little species of the same section as *G. tristes* and *G. cuspidatus*, which are characterized by small corms and rush-like or suberete foliage. The first named is now nicely in flower at Kew, corms of it having been obtained from the Botanic Garden at Cape Town, an establishment which now trades in rare bulbous and other plants native of that region. There is a poor figure of this *Gladiolus* in an early volume of the *Botanical Magazine*, compared with which the flowers on the plants now at Kew are much larger and of a softer canary-yellow color. They are borne on slender stems a foot high, and they have almost equal oblong segments spreading to a diameter of two and a half inches. As Mr. Baker says, this species is quite distinct from the other members of the genus in having so regular a perianth, a character which led to Solander classing it with *Ixiolirion*. Another name for it is *G. citrinus*. A dozen corms in a six-inch pot make a pretty little specimen when in flower at this time of year.

Sternbergia Fischeriana.—This plant has been introduced into England in quantity by Mr. E. Whittall, of Smyrna, some of whose bulbs are now in flower in pots and in the open border at Kew. It differs from the other species in cultivation in its habit of flowering in spring, and as the flowers are as large as the largest form of *Sternbergia lutea* and of a brighter yellow color, it is likely to prove a useful plant for the spring garden. There are three or four flowers on each bulb at Kew, and the flowers each last a week or more. The species is mentioned by Herbert in his *Amaryllidaceæ*, but he knew it only from a poor dried specimen. Mr. Baker does not appear to have seen good specimens of it before he published his book on Amaryllids. We have now three good garden *Sternbergias*, namely, *S. lutea*, a common plant in south Europe and northern Asia, which Clusius called the autumn-flowering *Narcissus*; *S. macrocarpa*, described by me in the last volume of *GARDEN AND FOREST* as having flowered at Kew from bulbs obtained from Mr. Whittall. This is a superb plant, as will be seen presently from the figure of it shortly to be published in the *Botanical Magazine*. Its flowers are nearly six inches across when wide open under the influence of bright sunlight, and they are of a bright golden-yellow color. The leaves are suberete, glaucous and very similar to those of the common Daffodil. The third is this spring-flowering species.

Snowdrops.—These are beautiful now on our lawns, among the rockery plants and along with the hardy Ferns. Many thousands of bulbs of *Galanthus Elwesii* were dibbled into the ground last October, and as soon as the thaw came to release them they sprang up quickly everywhere. I think they are most effective among the hardy Ferns, the rich brown of the dead fronds as they rest on the ground being a pleasing contrast to the pure white of the Snowdrops. Fadists who believe in making a species of every plant which deviates slightly from a given type would have no difficulty in finding at least a dozen among these thousands of *G. Elwesii*. One form in particular is worth notice, its leaves being glaucous and quite an inch wide, while its flowers have outer segments an inch wide and an inch and a half long. Of course, it is only a major form of *G. Elwesii*. Indeed, there are some who hold that this latter is nothing more than a form of *G. plicatus*. However, "let him name it who can, its beauty will be the same." Snowdrops are so cheap and they have so great a charm in the early spring, when largely planted on lawns, etc., that

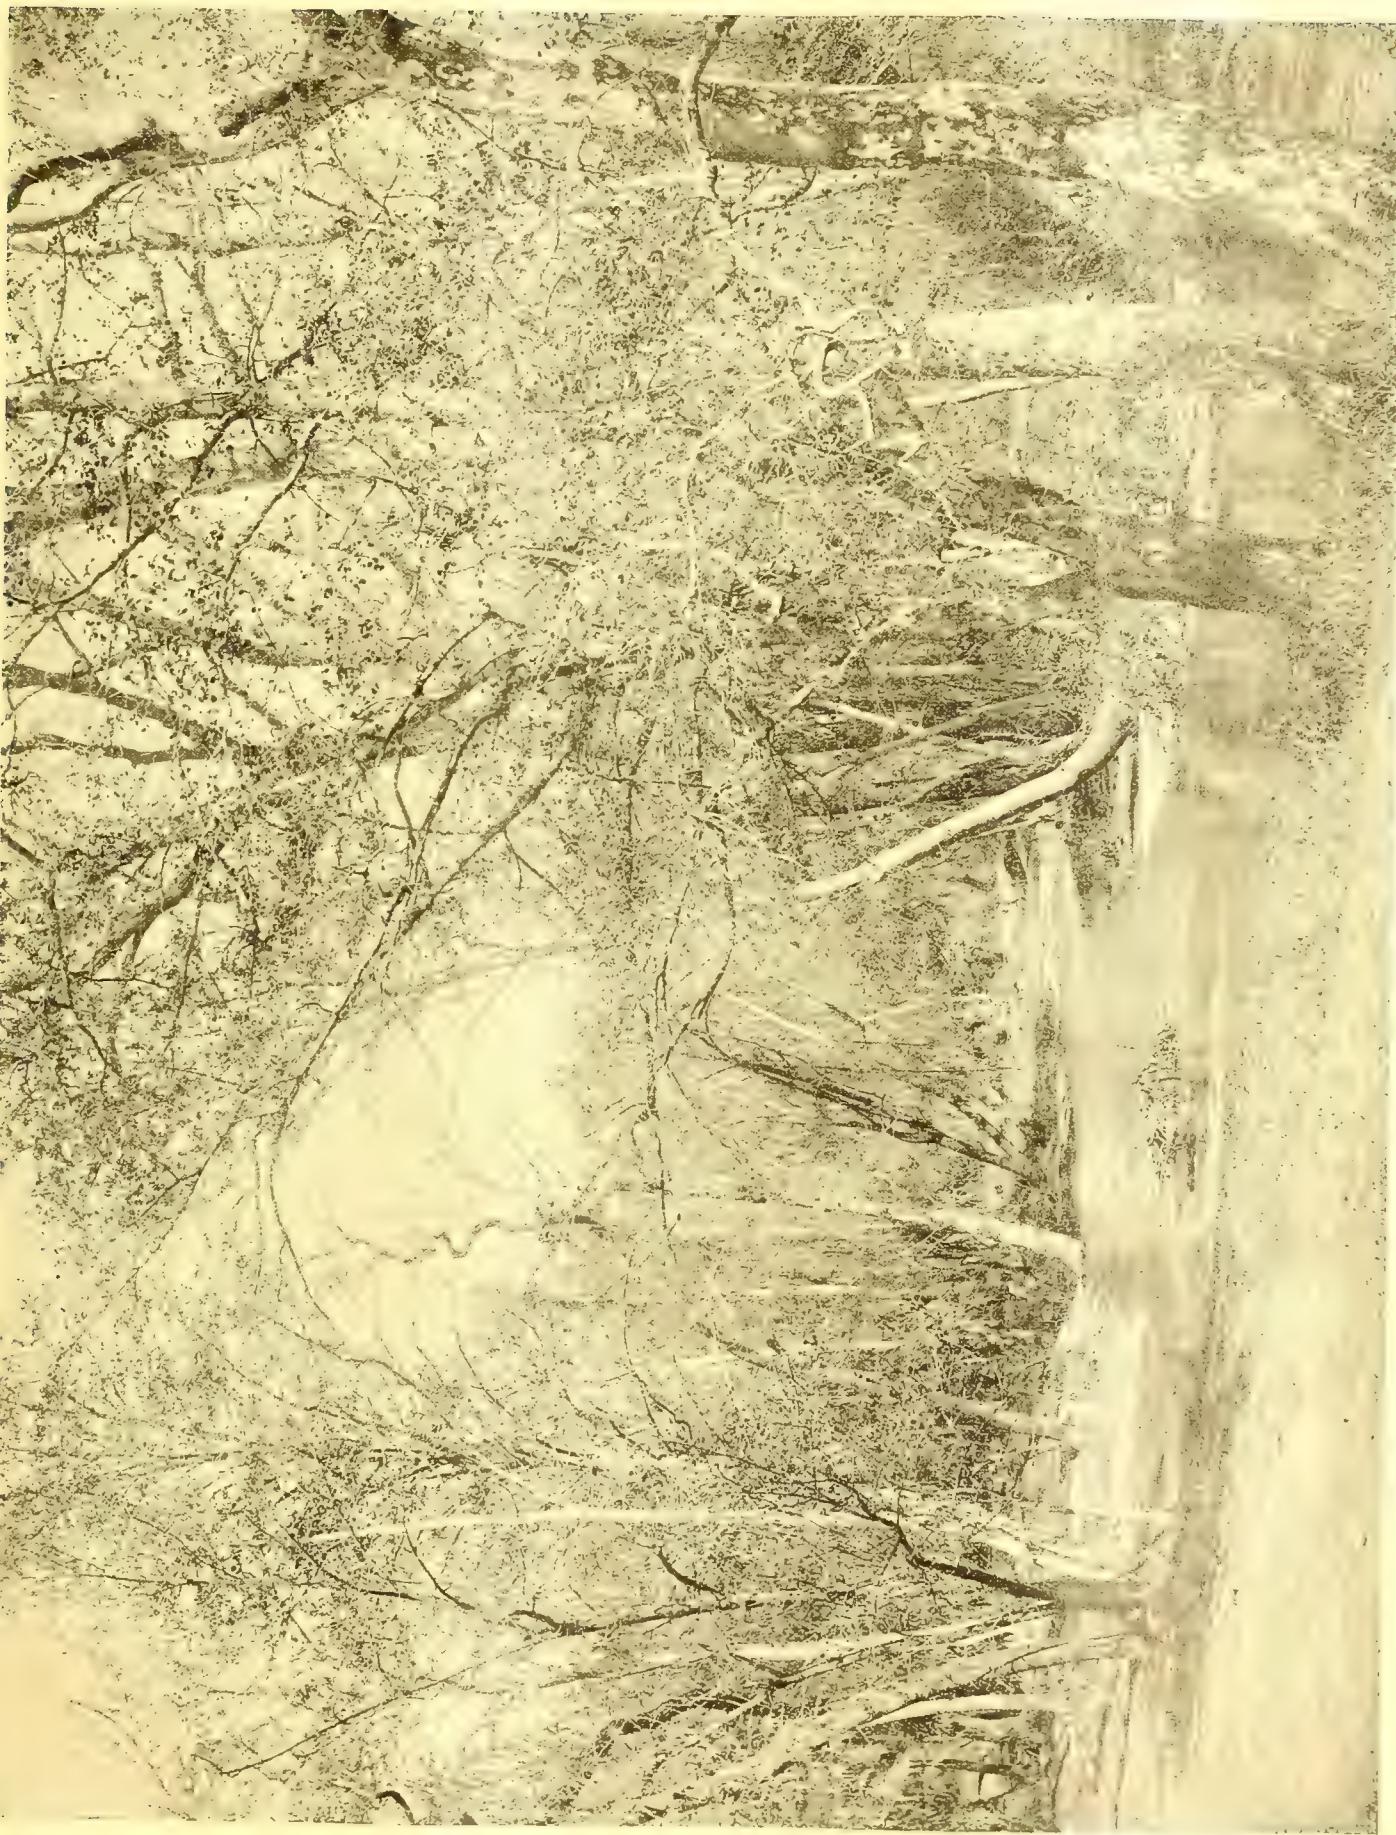

Fig. 23.—View on Chico Creek, Butte County, California.—See page 142.

every good garden should contain them in abundance. Even if they die after flowering every year, they are worth the little outlay in money and labor to renew them each autumn. The same is true of yellow Crocus and blue Chionodoxa, which are as largely employed and are quite as effective here as the Snowdrops. In some gardens these plants will establish themselves and multiply from seeds and offsets, but as a rule they fail to do this. The common yellow Daffodil behaves in the same manner. At Kew it will not live long if left to itself, whereas in some gardens known to me it is as independent of the gardener as the Dandelion.

London.

W. Watson.

Plant Notes.

AZALEA INDICA.—This old and well-known plant is now sold as a pot plant in such large quantities at this season of the year that it may be well to call attention to the fact that it has other uses than for Easter decoration. Indeed, there is nothing in the whole list of greenhouse plants more serviceable, more easily grown or more satisfactory. It is nearly hardy and can be safely and cheaply stored in a cold pit from which the frost is barely excluded; thus making it possible, without trouble or much expense, to hold in reserve a stock of plants which may be brought into bloom at any time from December to June, an important matter in greenhouse economy. Most of the plants now on sale are imported from Holland and Belgium; they are carefully trimmed and present a most symmetrical appearance; it is not at all necessary, as is generally the custom, to bestow so much labor and care in preserving these formal figures. The plant is thoroughly good if allowed to grow naturally; wire frames and numerous ties can be dispensed with. There is a method of growing them not generally practiced which simplifies, in a marked degree, the difficulties of handling Azaleas. They are planted out in a bright, sunny border early in May; the soil should be deep, well trenched and full of well-rotted manure; plenty of water should be given all summer—much the same sort of care one would give Carnations, Chrysanthemums or Violets in field-culture. A most vigorous growth will be the result of this treatment, astonishing to one who knows only the ordinary increase in pot-grown plants. If any one shoot obtains an ascendancy it must be pinched in; if suckers appear at the base, particularly in grafted plants, they must be removed, but staking in any form or tying is almost wholly unnecessary. In the autumn, late in August or early in September, they are lifted carefully and potted; they should be kept close for a few days and rather warm, after which they may stand in the open air until the nights are too cold, when they should be stored in pits and brought into the greenhouse in successive lots through the winter and spring. The result is not the formal type with which we are so familiar at exhibitions and in choice collections; but it is a healthy plant which looks like an Azalea and nothing else; the foliage is better, larger and deeper green, the flowers are quite as numerous and apparently of better size and texture. These Azaleas are good house plants; if the living-rooms are not too hot they will keep in flower for several weeks; care must be given to watering—if once they become dry it is difficult to restore them; if they can be kept in a cool room, an attic or bedchamber, before and after blooming, they will continue in good condition for years. It is unfortunate that the varieties now offered are largely double or semi-double; much of the grace of the flower is lost in their malformed petals; it is not sufficient compensation that they last a little longer.

MARICA CÆRULEA.—This Iridaceous plant from tropical South America is well worthy of cultivation, though the flowers, as implied by the generic name, are quite fugacious. The plant appears as a flat-clustered mass of sword-shaped leaves from an inch to an inch and a half in width and four feet or more high. The stems on which the flowers are borne at this season are of the same shape, and as

wide as the leaves, with a central vein. The flowers are borne from the side of this vein, near the top, on a small expanding stem, and appear in succession. They most strikingly resemble Tigridias in shape, with flat petals of bright lilac, and a depressed bowl, which is lined and striped with brown. This Marica grows well, and flowers regularly in a temperate house.

IRIS ROSENBACHIANA.—This Bokharan plant flowers with the Irises of the Reticulata section, although it is much larger and more showy. Its blooms are the most striking and distinct of the early Irises, and are variable both in size and color, red and blue purples and yellow being the prevailing ones. A very good form, sent to this office by Mr. Gerard, has falls of deep velvety red-purple, shading to a lighter tone of same on the claw, which is striped in two lines of dark color on each side of the bright orange-yellow ridge, which extends to the base. The crests are of an intermediate shade of purple, fading out on the styles, which are white beneath. The standards are small, spoon-shaped, and extend horizontally. The falls are slightly wider than the claws, but appear narrower, as they are partly folded usually. The claws and styles make a long tunnel, and Mr. Gerard observes that the bees, which are now active, have some difficulty in finding the nectar. They are deceived apparently by the open shape of the flower, and search around the base of the styles, neglecting the signals, which point the true way. This Iris belongs to the Juno section, with *Iris Persica*, etc.; and has a white-coated bulb with curious ovoid short roots, which would seem to be inverted offsets. The flowers appear in succession, usually two or three from each bulb, before the leaves. The leaves appear too late to be damaged by the frost, unlike others of the section, such as *I. orchiooides* and *I. Caucasicus*, and yet the more forward foliage of these plants usually suffers little, if at all.

HYACINTHUS CILIATUS (MUSCARI AZUREUM).—This deserves high rank among the earliest spring-blooming bulbs. B. M. Watson, Jr., of the Bussey Institution of Harvard University, writes that it was well in bloom during the last week of March in a bed planted with Crocus, Snowdrops, Iris reticulata, Bulbocodium vernum and many varieties of Squills and Chionodoxa; the Crocus Cloth of Gold, Bulbocodium vernum and the Snowdrops were its only companions in braving the cold winds and frosty nights of the season. Grape Hyacinth has been received for several years past from Van Tubengen, Haarlem, but it does not seem to be described by any of the gardening authorities on bulbous plants, nor is it generally offered in the trade lists. It resembles in its general habits of growth and flower the well-known *Muscaria botryoides*; the principal difference is that it blooms fully four weeks earlier and the flowers are much lighter in color, a beautiful robin's-egg blue. It is perfectly hardy and robust. Altogether it is a decided acquisition to our few very early blooming plants, and should be more frequently used.

Cultural Department.

Seasonable Work in the Flower Garden.

AFTER the severity of the past winter, there is not much doubt as to how to prune the hardy Roses, for with us they are killed down to the snow-level, and some lower still, but this has happened before, and the summer crop of bloom has not been much affected in the majority of kinds. Some of the weaker growers are sure to die out after hard winters, and this goes to prove that there are but few really reliable hardy Roses that can be planted in those parts of New England where arctic weather may be expected. A good coat of snow is the best protection, and if this is absent we always put straw round the roots, so that the plants may not be killed to the ground. It is best to cut off all dead wood as soon as possible before the sap begins to move and the buds to swell, pruning off at the same time all weak and useless wood that would not flower the coming season. We like to put on a sprinkling of some good commercial fertilizer and lightly dig it in after the beds are raked over; it helps to give the young buds a good start, and brings fine Roses later as well as good wood for next

year. We find it better to fertilize in spring than later in the season, for later applications have a tendency to produce fall growth that does not mature well, and often gets killed by frost. Besides this, the soluble parts of the chemicals, if applied late in the season, will leach out and wash away after growth is over, while if put on in spring we get its full value in the growth of the plants. Barnyard manures are good for new plantings of Roses, and would be good as a mulch all summer, but where it must be dug in to hide it, we prefer the commercial fertilizers, and avoid disturbing the roots of the Roses as much as possible.

Flowering shrubs need attention at this time; some need pruning back hard, like *Hydrangea paniculata*, to get good results. We find that this is one of the few shrubs that must be pruned back to a certain distance every year and all weak shoots cut out, and then strong flower-shoots come away; even these are sometimes reduced when too numerous. Nearly all flowering shrubs, however, are best not cut back in this way, or we sacrifice the growth that is to flower later. It is better to prune after the flowering period, if necessary, in all shrubs that flower in early summer. It is painful to see so often in suburban gardens, where the hired man has been round with the knife and reduced all the deciduous shrubs to a regular, or irregular, shape, regardless of the nature of the subject or of the possibilities as to bloom later. *Deutzias*, *Syringas*, *Pyrus*, *Wiegelia*, *Chionanthus* and *Rhus cotinus* are served alike, and the owners go on expecting some day to see a beautiful flowering shrub such as they see in the lists of tree agents.

One of the first things to attend to in spring is to reduce within reasonable limits such perennial plants as have a habit of taking up more room than is allotted to them. There are many good plants that offend in this way, and would soon overrun the garden if left a year or two. *Helianthus rigidus*, *Monarda didyma*, *Achillea serrata* and its variety, the Pearl; some of the *Spiræas*, as *S. lobata* and *S. palmata*; most of the perennial *Asters* and *Golden-rods*, *Boltonias*, and some of the *Coreopsis*, such as *C. tripteris* and *C. verticillata*—these, and many others which reproduce themselves too freely from seed, must be taken out remorselessly, or other plants of more value will be choked out before the summer is over, and too late to remedy the matter. We have often lost rare plants, not so much on account of their inherent weakness as because of the vigor of their companions. It is the old story over again, simply the survival of the stoutest.

As soon as the soil is in a fit condition to work freely the Pansies will be planted out in the flower garden, and in the mean time they are being kept as cool as possible to prevent the too early bloom that sometimes comes in the frames. The first crop is always the best, and we like to have this in the open ground, and to this end we cover our Pansies in fall with shutters and not sash, no leaves or straw is necessary, for this makes a fine harbor for mice, and when these shutters are taken off at the end of March the plants are in the best order to transplant in the middle of April, and will stand all the cold we get after this time. Last year we had snow on them for several days in the beds, but it did not hurt them a particle. We like to plant Pansies along the margin of the Rose beds; they do well in this rich soil where it is cool and moist; they are past about the time the Roses need to be cleaned up after flowering, and can then be cleared away. We have also a bed of Pansies by themselves each season, and too much cannot be said of these beautiful strains that are now offered at such reasonable rates, more especially those strains that are of French origin, Bugnots and Cassiers, and those known as the Parisian and Trimardeau are the highest development to which the Pansy need be brought.

South Lancaster, Mass.

E. O. Orpet.

THE work of cleaning up the flower garden after a long winter requires a good deal of care, and only experienced persons should be intrusted with the work. The customary practice of digging over the borders is a bad one, for, no matter how careful we may be, many plants just starting into growth will be injured. To put a spade or a fork into a clump of *Narcissus* and lift it partly out of the ground, as is often done, before it is seen, does incalculable harm, as growth with these, and all spring-flowering bulbs, commences in early autumn. Roots destroyed now will not be renewed this season. So it is with *Pæonies*, *Delphiniums* and all other plants not directly in sight. We find it better to put a mulch on in the autumn, and clear only the loose litter off in spring, breaking the soil only in places where renewals are to be made. A general overhauling, a replanting, and dividing of clumps which have grown too large, every three or four years will be often enough.

A few days ago I was sorry to see a lot of *Spiræa Thunbergii* and *S. Van Houttei* clipped "into shape." All flowering wood was cut away. Treated thus, I tried to think what splendid hedge-plants they would make. Those who can get over the idea of mutilation should give them a trial. No spring-flowering shrubs should be pruned in spring-time more than to cut out dead or weak shoots, or any that mar their graceful symmetry of form. Bushes of *Rosa rugosa* getting too tall, as they will when in masses, might be cut back. These will fill up the breaks quickly, and flower well by the autumn, but it is hard to make up one's mind to do this with such a charming and deliciously scented Rose, especially as it blooms so early.

We find sound wood of *Clematis paniculata* from ten to twelve feet above the ground, but consider it better to trim it back to within six feet. We also cut out weak shoots, and leave only a spread of the strongest. As it is a rapid-growing climber, it quickly covers a large space, and we have the trellis uniformly covered, where we would have only a congestion of growth at the top if it was left unpruned. Last season we worked in three or four pounds of commercial fertilizer about four feet away from the plants, and were rewarded by the most luxuriant growth ever made. One plant covered over three hundred square feet, and grew to the height of fifteen feet. When pruning the Chinese Wistaria, after it has made all the growth needed, we should select for cutting the long whitish spinous growths, and leave the shorter-jointed, darker-colored wood, which only produce flowers. It is important to make this distinction between ordinary running growths and flowering wood, as many amateurs make the mistake of cutting the latter out. Autumn-flowering shrubs generally bloom on the current year's growth, and may be safely pruned back if getting out of shape or straggly, as will happen in the case of the Rose of Sharon, *Hibiscus Syriacus*. *Hydrangea paniculata grandiflora* is another well-known shrub which can be cut back in spring to within two or three eyes of the old wood.

It is too early yet to overhaul the rock garden, but as soon as possible we shall clear up all dead matter and top-dress with a mixture of loam and lawn fertilizer. We use this in preference to common barnyard manure, which is usually full of weed seeds. Some plants will be dead, and against such a misfortune we make a sowing of new or selected kinds every year. Now is a good time to sow seeds of perennials and hardy annuals. Cold frames are best suited for this purpose. They are to be preferred to outside culture for the majority of kinds. Better attention is given in the matter of watering and shading when we have them under our eyes, so to speak. Sweet Peas ought to be sown as soon as the ground can be worked. It is not open here yet. Trenches such as we use for Celery do very well. This gives us a good chance to water thoroughly during dry weather. No plants suffer more from drought and more quickly go out of bloom if neglected. *Gladiolus*, *Crocosmias*, *Tritonias*, *Millas*, *Galtonias*, *Amaryllis* and other summer-flowering bulbs should be planted as early as possible, and the sooner hardy plants of all kinds are put out the better, so as to get them well established before the dry hot weather comes.

Wellesley, Mass.

T. D. Hatfield.

Nicotiana affinis.

NICOTIANA AFFINIS is a hardy annual now well known in gardens. It grows very vigorously in ordinary soil, attaining a height of three or four feet, and has strong thick roots. It produces rather thin dark green leaves, which decrease in size from the base upward. It produces in abundance tall flowering stems with numerous flowers borne on these at intervals of several inches. These flowers have long narrow tubes with spreading five-lobed corollas. The three upper lobes are crimped backward to the tubes, giving a unique character to the bloom, which is pure white, with a tinge of light green in the tube. Once grown in the garden it usually propagates itself by self-sown seeds, and these furnish often young plants in the late year, which will survive moderate winters. The most annoying limitation of *N. affinis* is that in the borders in summer the flowers open in the late afternoon and close in the morning, and the plants in midday are not attractive. Lately I have found that this plant is an excellent species for the conservatory and cool greenhouse, when at this time the flowers, curiously enough, do not close in the daytime, so that the plants are continuously attractive and scent the house with a delicate fragrance. As cut flowers they are also useful, and last three or four days perfectly in a warm room. Cut with long stems they have an informal look, and are very effective. They grow readily in a solid bed, and are

equally at home in a pot containing a liberal amount of good soil. *N. affinis* has also the merit of flowering for a long season, and might be useful to the commercial florist with a local trade, as it will certainly be appreciated by the private grower who enjoys something outside of the ordinary run of greenhouse plants. It is, of course, an inexpensive plant, costing nothing beyond the care of growing.

Elizabeth, N. J.

J. N. Gerard.

Strawberry Leaf Curl.

DURING the past year some visits have been made to Strawberry-fields complained of for a peculiar wilting of the foliage. The appearance is not easily described, but instead of the foliage remaining fresh and the leaflets horizontal, the latter bend up at the sides, lose their normal green, and assume a dryish and gray appearance. At first sight one cannot but think this behavior is due to a lack of water-supply; but the growers are firm in the opinion that plants in moist places suffer equally with those upon naturally dry ground. Many plants affected with the leaf curl were examined in the field, and nothing could be found at the root sufficient to account for the dried appearance. It was observed that, as a rule, the leaves showing the curl had a spot, sometimes several, upon the leaf-stalk often close to the clasping base. These spots are with an ashy centre and a purple border, and in general appearance resemble the "leaf spot," which, by the way, is usually found upon the leaflets of the same leaves. A microscopic examination drove away all doubt of any difference, and established the fact that the spots are due to *Sphærella Fragariae*, and probably cause a checking of the flow of sap, and thereby occasion the dried appearance. Such plants are seriously injured, because the fruit, depending as it does upon the foliage for its growth, must remain small and imperfect. It is not unusual for the fruit-stalk to be spotted like the petioles, and, therefore, such clusters are often worthless.

If the leaf-spot fungus, *Sphærella Fragariae*, an old enemy upon the foliage, is the cause of the curling of the foliage, it then brings the question of a remedy for the latter down to that of the eradication of the fungus. This can be done as has been demonstrated by the use of any of several fungicides as mentioned somewhat at length in previous articles upon similar subjects.

Rutgers College.

Byron D. Halsted.

Rose, Marchioness of Londonderry.—This comes to us as a new Rose of 1893, and it is one of the fine series which has emanated from the nurseries of Messrs. Dickson, of Newtownards, Ireland, during the past few years, and it has the distinction of having won the gold medal of the National Rose Society. It is hardy, with foliage that is at once a recommendation, being similar to that of the Ulrich Brunner, and quite as beautiful. The stems are also without thorns—a desirable feature in any Rose that has to be handled. The flowers are of the largest size, almost six inches across when fully open, of a most delicate shade of pink in the centre, something like that of the Daybreak Carnation, but paler, and shading from the centre to pure white at the edges. In all the English descriptions that we have access to, this Rose is described as pure white, but the pink shade is quite pronounced as grown here, reminding one of the old Souvenir de la Malmaison tint, and, indeed, it would not be surprising to learn that this plant has some influence as one of the parents of the Marchioness of Londonderry. The fragrance is similar also, and it has the smooth wood of the older kind. There seems to be no doubt that this new Rose will prove hardy, and it is listed as a Hybrid Perpetual, which is equivalent to the term Remontant. Both are unhappy terms as applied to outdoor Roses, as they rarely flower but once in a season. For forcing under glass the Marchioness of Londonderry can be highly recommended as being of a rare shade, pleasing, one of the largest Roses known, and as easy to force as Ulrich Brunner.

Those who have seen the new Rose Clio in London speak highly of it as a beautiful new white Rose. It is one of Paul's, and we may expect to hear more of it, since hardy white Roses are scarce.

South Lancaster, Mass.

E. O. Orpet.

Early-flowering Perennials.—Unless the greatest care is taken in moving this class of plants few flowers should be expected from them the first year, unless they are moved before their spring growth starts and a large amount of soil is taken with them. With every precaution, such plants as our native *Dicentras*, Spring Beauties, Dogtooth Violets and Trilliums had better be left until they have gone to seed. Some of them, however, like the Trilliums, when set out in early spring, make a better growth the second year than they would do if

the transplanting is deferred until autumn, when the leaf-buds have formed. There is a dormant period in the life of many early-flowering plants, especially those with fleshy and bulbous roots, which comes after their stems have died down, when they can be transplanted with little loss of strength. When the plant has begun to make growth in early spring, or when it is left until the autumn growth begins, the small roots are broken, and new ones must be formed, and this is always something of a drain upon its vitality.

Madison, N. J.

Correspondence.

The Opening of the Fire Season in Minnesota.

To the Editor of GARDEN AND FOREST:

Sir,—From the 15th to the 22d of March forest fires were frequent in the more open parts of Minnesota. The smoke from these so filled the air on the 22d as to make long sights with a surveying instrument impossible. These fires often originate, as has been stated and published many times, through a lack of intelligence on the part of people using fire. I lately noticed an instance that illustrates the effect of the proposed burning of tops after logging. The Eastern Minnesota Railroad Company had evidently instructed their section foremen to burn the brush on their right of way. There were but three men on the section, and with a track heaving by frost, and a great deal of brush along the line, they could not do the work properly. A fire was started in the brush, and the men went to dinner. Coming to the place a half-hour later, I found the fire running rapidly through the adjoining Pine.

In Minnesota most of the railroad companies have large grants of land for sale, and it would be a good policy for these companies to clear and cultivate the land along their tracks, both to illustrate what can be grown on the lands they have for sale and to keep the fires from spreading from their tracks and killing their timber. The evidence that fires started from locomotives last summer can be found along nearly every mile of track, and it must be that stockholders in these companies are not aware that they are doing themselves great damage by letting these fires escape.

Carleton, Minn.

A.

The Cherokee Rose.

To the Editor of GARDEN AND FOREST:

Sir,—The article in your issue for March 20th on the Cherokee Rose encourages me to relate a most satisfactory experience with the same plant. Some two and a half years ago I set Cherokee Roses along a fence consisting of seven barbed wires, some eight inches apart, and therefore about eight feet high. The plants were set at a distance of fifteen feet apart, and grew well, although I took care that they should be trained along the wires. By this process I soon had a fence which is hardly thicker through than the wire, and which is marvelously beautiful as it stretches along the road. It blossomed within the first year after planting, and produced in the second year such a mass of flowers that it seems as if covered in snow. During the past unfortunate winter it was three times badly set back by the frost, and though it showed flowers in the first week of February, a severe frost on the eighth of that month checked it again for weeks, although it was never deprived of its leaves, and as it ran between dead and brown Orange groves it was the one redeeming feature of the landscape, as it is to-day in a much higher degree. During the past three weeks it has made a full growth of new foliage, and the flowers, which came forth sparingly, now cover the fence from top to bottom. I have planted two miles of it, and it not only gives a great deal of pleasure, but it seems to be a fence which, while not thicker than a man's hand, is absolutely secure against man and beast. It has been grown without any trouble, only requiring the first careful training, which the plant easily follows. Later on it will undoubtedly require the cutting out of the older wood. Some of my neighbors flatter me by saying that this is the only instance they have ever seen where a barbed-wire fence has been transformed into a thing of beauty.

Maitland, Fla.

D. F. L.

Forestry at the Michigan Agricultural College.

To the Editor of GARDEN AND FOREST:

Sir,—Michigan has not attempted any work of consequence in forestry, although every dollar intelligently expended in this direction would return to the state in increased value. People take it for granted that nothing can be done to improve forest

interests. No one cares to study forestry, and our legislators, as a rule, oppose all bills which involve expenditures of public money except in relation to matters in which they are personally interested.

A small plat of two acres of trees in rows was started about eighteen years ago on our college farm, and has proved of considerable interest to a few persons. This farm, which originally contained rather more than a square mile, and consisted almost entirely of virgin forest, has been cleared, until now little more than two hundred acres remains of what, by a charitable construction, may be termed woodland. Owing partly, perhaps, to frequent changes of professors of agriculture in the College, who had control of both the cultivated fields and the woodlands, there has been no settled system of management of the forest. During the past winter the State Board of Agriculture conferred with the Professor of Forestry and with the Professor of Agriculture, and it was decided to attempt some systematic improvement of the College woodlands in an unostentatious and inexpensive way. South of one of the two railroads which cross the rear part of the farm is a tract of seventy-five acres, considerably broken by a marsh and many small cat holes. This has been cut over from time to time and in places some of the undergrowth has been killed by fires, while many seedlings and sprouts have been destroyed by cattle and sheep, while the inroads of grass have been encouraged. This area is to be cleared of all woody growths and the land subdued by pasturing and crops, and then the whole plat is to be planted with trees, according to what is recognized as the most scientific practice. Another section of seventy-five acres is more heavily timbered, much of it with Beech and American Elm. A strip on the north-east of a fence adjoining a railroad track has been cleared. This will be pastured by sheep for a year or two and then back-fired in such a way as to help in preventing fires from getting into the woods. The considerable quantity of Oak on this tract was removed four years ago, as the trees were losing rather than gaining in value. A tract of fifteen acres to the north was nearly cleared of timber some years ago, and all the trees larger than a man's arm that remain will be removed, so that the young trees and sprouts can have a good chance to grow evenly and occupy the land. Farther to the north, and separated from this tract by fields in cultivation, is a narrow strip containing fifty-four acres of good land, and here is the best timber standing on the farm. The strip is longest from east to west and slopes to the north adjoining Cedar River. A space four rods wide will be cut north and south through the middle; this will be kept clean and will illustrate one method of preventing the spread of fires, and at suitable times it will be back-fired.

From all this land which is to be retained in forest the old logs and dead brush should be removed or burned in open places. None of it has been pastured, and it contains a fine growth of young timber in variety. The whole tract has been surveyed and staked off into plats of some ten acres each, and a record will be made of the present condition of each and notes will be made of all future operations. Not a conifer can be found, with the exception of a few small Tamaracks, on any of these tracts. Native coniferous trees in variety will be planted in open places which suit them, especially in the narrow strip of a river. It is not expected that each plot will be treated alike. In a few slightly shaded places where the soil is light and dry, seeds of the common Locust will be sown or sprouts planted. We are induced to try the Locust in this way, since a few of these trees growing in our arboretum are now large enough to make good telegraph poles, and yet they are only twelve years old from sprouts.

There are other areas of woodland, one of them a piece of rough new ground which we proposed to turn into woodland, but there is no need to give any further details. My purpose in writing is to show that we are preparing here to have some practical instruction in forestry, and to invite suggestions as to the best method of managing our woodlands.

Agricultural College, Michigan.

Recent Publications.

A Popular Treatise on the Physiology of Plants. By Dr. Paul Sorauer. Translated by F. E. Weiss. Longmans, Green & Co., London and New York.

This title is not of itself sufficiently descriptive of the book, which is not only a treatise on plant physiology, but a treatise prepared for a special purpose—namely, "for the use of gardeners or for students of horticulture and of agriculture." Professor Sorauer is something of an authority

in certain branches of botany, but he was also for years director of an institution for the scientific training of gardeners, and, therefore, in preparing his book he not only aims to describe the various organs of plants, with their functions, but to show how these scientific principles can be put to practical application. Of course, general students of botany will find in the book what is to be expected in a treatise on vegetable physiology, but its primary value lies in the fact that it has been written expressly for students of horticulture, and it constantly sets forth the scientific reasons for the best practice in propagating and cultivating plants. The opening paragraph of the book states that a gardener should not look upon a plant as unchangeable and restricted to a definite form, but as a plastic organism, capable of modification in all its parts. He should, therefore, be acquainted with the various functions of the plant, so that he may know how to regulate the conditions of its life in order to effect such changes as will adapt it most successfully to specific use. He must know the processes and the reasons for them which cause hard roots to become thick and succulent, as in the case of beets, and hard fruits to become large and juicy by an increase of their softer tissue, as in the case of apples and pears, and, in general, how to modify and change, where it is necessary, the normal development of a plant, as well as to cultivate it in its natural form.

Professor Weiss, who translates the book, after undertaking a course of lectures on vegetable physiology at the Botanical Institute in Manchester, England, realized the need of some work which combined science and practice in this natural way, and as there was no such work in the English language he translated Professor Sorauer's book, and thus has laid English students of horticulture under obligations. Now and then we find an apparent lack of familiarity with the very latest discoveries of science. The book, however, may be trusted as substantially accurate, and it has a special value because the practical use of this scientific truth is constantly borne in mind. For example, the author does not simply show what nutritive substances are needed by a plant, but he sets forth in detail the ways in which these should be prepared and administered to serve the best purpose. When it is explained that the roots of plants need air, it is also explained how the soil should be handled to meet this requirement. When the student is told how roots should be treated in repotting and transplanting, the reason for every step is added, and all the ordinary processes in horticultural practices are discussed in the same way. It would be difficult even for a skilled horticulturist to read the chapter on the Philosophy of Pruning, or the one on the Different Methods of Propagating from Shoots, without obtaining some ideas which would help him to do his work more intelligently and efficiently. Altogether, the book can be commended as a thoroughly useful one in a hitherto almost neglected field. It is a matter of regret that Professor Weiss did not go a little beyond mere translation and bring the science of the book thoroughly up to date in every point.

Notes.

Trim plants of *Boronia heterophylla*, with their bell-shaped little flowers of brilliant carmine or crimson, have become quite common as plants for Easter decoration. It is an Australian shrub, resembling *B. elatior*, but much neater in habit and more floriferous.

Among the cut flowers now coming from Bermuda are spikes of *Gladiolus*, most of them being those of the variety Shakespeare. These flowers did not arrive in very good order, but well-flowered spikes arriving in good condition at this season would, no doubt, have some depressing effect on the flower market here.

A dried plant of the new Sweet Pea, Cupid, seeds of which are to be disseminated by Burpee, of Philadelphia, next year, shows that the plant grows about ten inches high, and spreads out into a close bushy head, some fifteen inches across and

covered with white blossoms. Of course, the stems of the flowers are not as long as in the climbing Peas, but there are many places where the dwarf plant can be used to advantage, and there can be no doubt that the California paper is correct which declares that it will make an interesting pot-plant.

A Dutch horticultural journal says that an excellent way to preserve fresh nuts is to place them, immediately after gathering, in clean flower-pots, the holes in which have been stopped, and, covering them with a tile or bit of slate, to bury them in the earth until they are needed for use. The main thing is to protect them completely from the action of light.

The delicate and remarkably sweet-scented flowers of *Chimonanthus fragrans* are often fully open in latitudes south of Philadelphia in February. Mr. Joseph Meehan writes that he has been watching for the appearance of these flowers for some time, and, in his disappointment, has at last examined the shrubs closely, to find that the buds had all been destroyed by the frost, sometimes when they were about half-open. There are flowers on the prostrate stems of *Jasminum nudiflorum*, but the buds on the upright-growing shoots are still tightly closed.

Professor Wood, while he was a member of the staff of the New Hampshire Agricultural Experiment Station, made some tests with regard to the flow of maple sap which are of interest. Maples are usually tapped to the depth of about an inch, and this practice is based on the belief that the sap comes chiefly from the wood of recent growth, so that any tapping deeper than the layers made during the last six or eight years is useless labor and an unnecessary injury to the tree. Professor Wood's experiment, however, seems to show clearly that the flow of the sap is largely dependent on the depth of the tap, and that sugar-makers may with great profit tap their trees to a depth of four or five inches. The additional injury to the tree is slight, especially if the hole is small, and when a three-eighths of an inch bit is used and the bark is left uninjured, the holes will be grown over the first summer after tapping. It seems that twice the amount of sap can be obtained by tapping four inches deep instead of two, while the sap from deep boring is almost as rich as the other. The exposure of trees to the sun has much to do with the result from tapping on different sides, and there is little doubt as to the correctness of the popular view that the trees should be tapped on the south side wherever practicable.

In a recent lecture, Mr. D. Morris, Assistant Director of the Royal Gardens in Kew, noted the fact that the commerce in vegetable fibres was one of the most important in Great Britain, and that the imports in 1893 amounted in value to forty-five millions sterling, and the export of manufactured goods reached a value of seventy-four millions sterling. Of imports, nearly all the cotton, flax, hemp and paper material came from foreign countries, and it seemed to Mr. Morris a matter of regret that Canada could not become a great flax-producing country, that New Zealand did not improve its phormium production for the higher class of textiles, and that cotton and ramie were not grown in the West Indies. Cellulose is the essential element in all fibre. Cotton, sola pith, ivory nut, linen rags were all cellulose, and in the Kew Museum fragments of linen cloth found between bricks of pyramids erected twenty-five hundred years before Christ, showed that in a dry atmosphere cellulose is practically indestructible. One of the new fibres, especially interesting and quite unknown in Great Britain, is to be seen in a cuirass made from a kind of wild pineapple, and this suit, worn by the Indians of South America, is padded before and behind with vegetable silk from the fruit of the Yachan, *Chorisia insignis*. By rolling themselves in water the silk swells until the cuirass becomes arrow-proof.

Since the best teachers of science in these times insist that their pupils shall study objects before they receive much instruction from books, instructors of botany find it difficult to procure at any given season of the year enough fresh material to fully illustrate different subjects. In following any textbook, for example, enough specimens to illustrate the different sections of the book as they are taken up at different dates, can rarely be found. To obviate this difficulty, Professor Beal writes to *Science* that he has collected quantities of stamens of different plants, say, the Barberry, Sassafras, Lobelia, Cypripedium, etc., and preserved each kind by itself in a solution of twenty-five per cent. alcohol, or of one of formalin to one hundred of water. These specimens are all ready when the subject of stamens comes to be studied, and the preserved objects can be placed in a small dish before the pupils when

fresh specimens cannot be procured. If they are not allowed to dry they can be used for successive classes. In the same way Professor Beal has preserved forms of pistils, the torus and other parts of plants, including fruits of various kinds, such as half-grown plums or cherries, fruits of the Mandrake, Bloodroot, Mulberry, etc., at different stages of growth, and in this way lessons in morphology can be made more impressive than they would be if one illustration was used at one time, and the others a week or a month later.

Among the pears in market the Winter Nelis, with its beautiful gray-russet coat, fine-grained, buttery flesh and rich aromatic juice, is still to be found in limited supply. Easter Beurre, though not so beautiful, is much larger and is always prized for its melting quality and rich flavor, and good pears of this variety now sell for \$1.50 a dozen. P. Barry is hardly yet at its best. It is a large and beautiful fruit with a vinous flavor, but its flesh is somewhat stringy, so that it can hardly be called a pear of the very finest quality. It commands as good a price as Easter Beurre, however, and will be the leading pear in the market when all others are past their season. The finest apples here now have been coming from Vermont and have sold for exceptional prices. These have been Newtown Pippins, Northern Spies and a few extra Baldwins. The crop of Washington Navel oranges, from California, is so nearly exhausted that prices have grown rather more firm, and fair fruit sells for \$3.50 a box and upward. There are practically no seedling oranges from California in this market. They are met half-way across the continent by West Indian fruit, which commands fully as much in Chicago as the California product. Good Washington Navel oranges retail for sixty cents a dozen, Messina Blood oranges for the same price, and the best Jamaicas for fifty cents a dozen. Almeria grapes, if in large clusters and finely colored, bring fifty cents a pound. In spite of the arrival of the large supply of tomatoes which is coming from southern Florida, Cuba and Bermuda, solid hothouse tomatoes sell for seventy-five cents a pound. String beans, from Florida, bring \$8.00 a crate at wholesale, and green peas from the same state bring \$5.00. Asparagus is now coming from as far north as North Carolina, and is worth seventy-five cents a bunch. Florida is sending new beets and new cabbage. From Bermuda are coming new beets, carrots, onions and parsley. The best hothouse cucumbers are from Boston, and bring \$2.00 a dozen.

Ignatz Forsterman, one of the most enterprising and accomplished of the commercial florists in the vicinity of this city, died at his home in Newtown, Long Island, on the 29th of March. Mr. Forsterman was born in Coblenz, Prussia, in the year 1854, and after studying in the Garden Institute, in his native city, he acquired facility in the practice of his calling in various horticultural establishments of his native country, in Switzerland, France and England. He became specially skilled in the cultivation of Orchids, and by his habits of close observation he acquired a very comprehensive knowledge of these plants and their habits. In the year 1881 he began a series of remarkably successful collecting tours for an English firm, and sent home many new plants from India, the Malayan Archipelago, Burma and other parts of Asia. His knowledge was supplemented by such energy, industry and fearlessness that no labor or hardship discouraged him. The trying climate, however, undermined his strong constitution, and since he settled in this country in 1886 his health has always been delicate. He bore this burden, however, with cheerful courage, and, in spite of many drawbacks, he established a prosperous business, some features of which were absolutely unique. He became a large importer of such Orchids as could be profitably grown for cut flowers, and sold them in quantities to florists who grew them for market flowers, while at the same time he did not allow his collectors to neglect the search for valuable rarities. Among the best-known Orchids which he personally collected was *Cypripedium Spicerianum*, which he rediscovered; *Dendrobium Sanderianum*, *D. cruentum*, *Cœlogyna Sanderiana* and *C. Forsteriana*; *Cypripedium Sanderiana* and many others, besides such interesting plants as *Pteris Victoriae*, which has become a universal favorite. Besides these he discovered a number of species and varieties, specimens of which are now locked up in the Reichenbach herbarium.

The death of Mr. Forsterman is a genuine loss to horticulture, but those who knew him best will miss him more for his high moral qualities than for his helpful knowledge in his chosen pursuit. He was a man of singular gentleness of disposition, modest, truthful and unselfish. His ability always commanded respect, while the genuine worth of his character won the esteem of all who knew him.

Public Reservations in the State of New York.

FOUR years ago a body known as the Trustees of Public Reservations organized under an act of the Massachusetts Legislature, for the purpose of acquiring and opening to the public, under suitable regulations, beautiful and historical places and tracts of land within that commonwealth. The establishment of this commission was the act of an enlightened community. It was a step forward, and offered an example and a challenge to the public-spirited people of other states to adopt similar measures, until it shall become a recognized policy throughout the country to preserve for posterity the natural beauty we have inherited, and to protect for the inspiration of future generations all those places which are rendered sacred by patriotic memories. Of course, there have been sporadic efforts in this direction all over the country. Pennsylvania has the camp-ground at Valley Forge; New Jersey has acquired the fine old colonial mansion and grounds at Morristown, where Washington held his headquarters, and this state has taken possession of Niagara and has made some effort to save the Adirondacks. But the Massachusetts plan has the advantage of being comprehensive and complete. No special legislation is demanded. The trustees can accept donations, purchase property, make necessary regulations for the maintenance of these reservations, and have all power necessary to acquire and preserve for public use forever any places which it may be desirable to secure.

It is an encouraging fact that the Legislature of New York has also taken action in this matter, and that Trustees of Scenic and Historic Places and Objects have been organized under law in this state. This result is largely due to the labors of Andrew H. Green, Esq., of this city, who is especially desirous to keep from defacement and ruin certain localities of historic interest in the upper part of this city and elsewhere in the state. In his original memorial Mr. Green called attention to the fact that there were many places in this state made memorable by conflicts during the half century of the French and Indian wars of the colonial

era and by the stern conflicts of the Revolution, and, besides these places which are hallowed by their connection with the past, the varied topography of the state includes landscapes of world-wide celebrity, water spectacles and picturesque islands, incomparable lake areas, wooded mountain ranges and scores of picturesque valleys, which ought to be preserved in their primitive beauty. This Board of Trustees has organized in a practical and business-like way, with Mr. Green for President; John N. Francis, of Troy, for Vice-President; Edward P. Hatch as Treasurer, and John Winfield Scott as Secretary. The incorporators are all men well known for their public spirit, and as they come from all parts of the state it is expected that through their influence local historical societies, town boards and private individuals will be stimulated to coöperate with the trustees.

We need not add that in our view of the case this action of the state of New York is far removed from anything trivial or merely sentimental. We believe that the opportunity to drink in the quiet delights of natural scenery is more and more a necessity, especially to the thronging laborers in our busy towns, and that the contact with natural beauty is distinctly refreshing and uplifting. We also believe that places hallowed by patriotic action and suffering, minister directly to the mental and moral health of the people by the appeal they make to our generous passions. Americans are sometimes inclined to reproach themselves for possessing less interest in the past than that which prevails in the older civilizations of Europe, but it is little more than a year ago that a society precisely like those we are discussing was formed in England for the purpose of protecting scenes of natural beauty and historical renown from being vulgarized and ruined. Quarrymen are defacing the Palisades in our own country, but Cheddar Cliffs are suffering in the same way in England, and the necessity of coöoperating to protect such places has been felt in England just as it has been in Massachusetts and New York.

Every public-spirited citizen of the Union ought to realize the fact that many places in the country around which interesting memories cluster are in danger simply because there is no custodian to whom they can be legally transferred, and by whom they may be guarded. The disfigurement of natural beauty will go on, old landmarks will be destroyed and old earthworks leveled under the plow whenever they come under the ownership of men who have no feeling for their beauty or interest. Every state ought to make haste to pass a law incorporating a body like these trustees. The good work accomplished by such a body will not cease with the simple protection of a spot here and there. It will invite the attention of all who visit and enjoy these places to their value, and it will develop a sentiment which will grow by exercise, and will assist to a certain extent in inspiring the people with something like a reverent regard for natural beauty wherever it is found. If this sentiment ever becomes as pervasive and vigorous as it should be, there will be less need to set apart special reservations, for all the people will be prepared to rise against the obliteration and defacement of natural beauty. The vandalism of the advertiser will cease, the great corporations will no longer needlessly mar the most pleasant prospects in operating their mines and quarries and railroads and factories, and each generation will feel it a sacred duty to leave the world to their successors as fair a dwelling-place at least as they found it.

A MOVEMENT is on foot to commemorate in some appropriate way the genius of Francis Parkman. As a historian, as a man of letters, as a true hero who added dignity to American scholarship in spite of life-long physical limitations, Francis Parkman deserves a grateful recognition by his countrymen. It would hardly come within the field of this journal, however, to invite attention to this movement if Francis Parkman, in addition to his other claims to

distinction, had not been eminent as a horticulturist and untiring in his efforts to preserve our rich inheritance of natural scenery. No pen has described the grandeur of our primeval forests with such poetic truth as his; no man ever loved nature more sincerely. In the very first number of this journal he made an eloquent plea for the protection of the forests of the White Mountains, and till the day of his death this subject was one in which he took a vital interest. This movement, however, makes appeal in a still more direct way to every one interested in horticulture as a fine art. It is not decided what form this memorial shall take, but it is proposed to erect it in the garden that Parkman loved, on the banks of Jamaica Pond, which has now been taken as a part of the Park system of Boston. Here, thirty years ago, he wrote the *Book of Roses*, which remains a standard authority in many branches of this subject to this day. Even before this the first collection of plants sent to America from Japan was planted in this garden, including the beautiful double-flowered Apple which bears his name, and many other plants now well known to our gardens. Here was established one of the very earliest good collections of hardy herbaceous plants in the country; here he made those experiments in hybridizing and cross-breeding which were described in one of the most interesting horticultural papers of its time. It is altogether fitting that every American who loves garden-art should have the privilege of contributing to this memorial of one who holds such a distinguished place in the development of horticulture in America. Contributions can be sent to Mr. Henry L. Higginson, 44 State Street, Boston. The committee in charge are men of cultivated taste, and there is every assurance that this memorial, whatever it may be, will not lack adequate dignity and refinement.

Park vs. Grove.

A FASHION is prevalent in some western states which is of enough importance to warrant some comment, and if the mental derangement which it seems to indicate can be properly diagnosed and treated, the undertaking will be worth a great deal to many communities. Now, there are very few real parks in western towns, unless delightful bits of virgin scenery are to be accepted under that head. The pleasure-grounds where, with natural conditions more or less propitious, an intelligent art has wrought any satisfying or pleasing effect, are exceedingly rare. At the same time there are not wanting hundreds of attempts in this direction. Almost every prairie town of any consequence at all has its so-called park. Sometimes this park and the fair-grounds are combined. Whether the park be fair-grounds, race-track or plain park, however, the location is usually upon some thoroughly flat, featureless and treeless plat, where the City Council and the Street Commissioner can give their creative instincts full swing. This park is laid out in intricate and wonderful patterns. It contains race-tracks, baseball grounds, camp-meeting stands, carp ponds, fountains or fences, according to the whims of the Street Commissioner and the demands of the populace. It is profusely set with trees, Cottonwoods having a large majority, and these are then left to struggle with a magnificent annual crop of Sunflowers. This picture is not in the least overdrawn. Any one who has ever lived in the west knows it to be the sober truth. As a consequence of the construction and maintenance of this park it is unfrequented and neglected. If the county fair is held on the grounds in the fall the Sunflowers are mowed, and for three days the park is crowded and useful.

Now, it is a strange companion picture to this which one sees if he visits "The Grove." Near most towns will be found pieces of natural woodland, usually along some stream, to which the picnic parties always turn with a natural impulse, which largely discredits their ill-conceived ideas of a park. Every town has its "Wilson's Grove" or "Johnson's Grove," which is a place of this sort—virgin

woods and streams and rocks, unmarked by any attempt at art. This is the place to which the citizens all retreat when the appetite for fresh air and shade and outdoor rest is to be satisfied.

The name Grove, as applied to this picnicking rendezvous, in contradistinction to the Park, is of some interest. These terms are commonly accepted and used with the utmost clearness of distinction, showing that in the popular mind the two articles are in no way related. Nevertheless, it would appear at once to the artist in landscape that the grove is by far the more satisfactory park. And were the parks of western cities planned by landscape-artists there is no doubt but that they would usually be located where unperverted instinct has found a satisfying grove, and seldom or never where false instruction has led citizens to make their so-called parks.

I have in mind one particular western village of more than usual culture and enterprise, which may, however, be taken as an example. This town has expended many hundreds of dollars in making a park on forty acres of valuable land. One corner is kept mowed for a baseball field, and this is the extent of the use found for the park. Quite as near the town, on the opposite side, are uncommonly fine stretches of natural timber, a beautiful river, suitable for boating and bathing, some hills and ravines, which would make a delightful park. These woods, used otherwise only for pasture, constitute The Grove; and to them comes the crowd for the soldiers' reunion, the picnic, the circus, and so forth.

Many times delightful results might be obtained if the work which has been put on a city park could have been judiciously expended on The Grove. And this shows us the direction in which lies the remedy. The existence of the park shows the public spirit and liberality of the citizens. The general favor in which the grove is held demonstrates the unspoiled instinct for sylvan pleasures. The solution of the difficulty would be to unite the two, and here is a problem worth attacking.

F. A. Waugh.

The Banksian Pine in the Nebraska Sand Hills.

SO far as I know there has been but one experiment made with *Pinus Banksiana* in the plain region. In 1891 the Chief of the Forestry Division furnished Mr. H. C. Brunner, of Holt County, Nebraska, enough trees to plant three experimental plats of one acre each on the crest and slopes of one of the highest sand hills in the entire Sand Hill region of Nebraska. One of these plats was planted principally to Banksian Pine, the remaining species being other conifers.

This Pine was chosen because it thrives on the sand dunes of Lake Michigan, and the soil conditions of the two localities are not dissimilar, consisting of an almost pure sand. In a visit to the Nebraska plantation last October I was surprised to find the sand quite moist only a few inches below the surface, on the crest of the ridge, in spite of an unbroken drought of months. The trees were four to six inches high when planted. Practically, all the other species failed, only a few Scotch and Bull Pines showing where hundreds had been set. But the Banksians had thrived. While yet three miles from the plantation they were easily discernible, a green patch on the very crest of the brown sand hill. Examination showed that over half of the trees, which had been planted two by four feet apart, were in thrifty condition, ranging from ten inches to almost four feet in height. The best growth of the year was eleven inches. The trees had been set in a furrow made in the unplowed sand, on which grew a scant herbage of grasses. Had the plat been plowed the sand would have blown away, as is proven by the many "blow-outs" seen while crossing the Sand Hills from Burwell to Ainsworth. The scant vegetation held the sand in place, and the Banksian Pine had become established. Barring unforeseen accidents, there is sure to be, in the course of twenty years, a tiny Pine grove in this vast desert region, devoid of trees and

only useful for the splendid growth of grasses in its valleys.

The Banksian Pine has a great northern range, being found from Michigan north-westward through Minnesota and into Manitoba, but it is not a native of the plains region. In standing where a great percentage of Bull Pine failed—the latter being native within sixty miles—it not only shows peculiar adaptability, but suggests its extensive use as a pioneer tree throughout the sand hills of Nebraska—a region from thirty to sixty miles wide and over two hundred miles long.

London Letter.

BULBOPHYLLUM GRANDIFLORUM.—A plant of this was shown in flower last Tuesday by Sir Trevor Lawrence under the very inappropriate name of *Bulbophyllum Burfordense*. It was first figured and described by Blume in *Rumphia*, iv., page 42, where it is said to be "wild in woods on the coast of New Guinea. Flowers the largest of the genus, above eight inches in diameter; scape six inches high. The dorsal sepal brownish and netted with a paler color, the others not netted. Lip whitish, with red spots." The flower on the plant shown by Sir Trevor Lawrence had a concave sepal four and a half inches long and two inches broad, the two lateral sepals being narrower, but quite as long. the petals and lip being small and inconspicuous. The color of the dorsal sepal was yellowish green, with gray mottling and darker veins, the other two being dull pale brown, with a gray reticulation. Rhizome as thick as a goose-quill, the pseudo-bulbs an inch apart, narrow, ovate, an inch long, each bearing an oblanceolate leaf eight inches long by two in width. Although wanting in color, this is one of the most remarkable Orchids introduced in recent years. Sir Trevor obtained it from L'Horticulture Internationale a few years ago, this being the first time it has been seen in flower in Europe. There is, however, another *Bulbophyllum* of this name, a figure of which will be found in *Lindenia*, vol. iii., t. 108 (1887), and which had been introduced from New Guinea by Monsieur Linden, and flowered in his nursery. Reichenbach identified this with Blume's plant, an extraordinary blunder, the two being very widely distinct. For the latter plant Mr. Rolfe proposes the name of *B. longisepalum*, on account of its very narrow attenuated sepals. Both, however, belong to the same section, namely, *Sarcopodium*.

BOLLEA SCHROEDERIANA.—This is a new species, according to Messrs. F. Sander & Co., who have lately introduced it, and who showed it in flower last Tuesday, when it was awarded a first-class certificate by the Royal Horticultural Society. It was a fine specimen, bearing eleven large fragrant flowers with white sepals and petals, flushed at the tips with rose, and a pink labellum, which had a short claw and a thick boss-like crest. Botanically it belongs to the *Zygopetalums*, but for garden purposes the sectional name, *Bollea*, is convenient.

DENDROBIUM CORDELIA is a new Veitchian hybrid between *D. aureum* and *D. euosmum leucopterum*, the latter being the seed parent. It most resembles *D. aureum*, the sepals and petals being cream-white, with a tinge of rose on the margins, the lip being purplish, with yellow blotches and veins. It received an award of merit. The "pedigree" of this hybrid is as follows: *D. Japonicum* × *D. aureum*—*D. Endocharis*; *D. nobile* × *D. Endocharis*—*D. euosmum*; *D. aureum* × *D. euosmum*, var.—*D. Cordelia*.

DENDROBIUM HILDEBRANDII.—We are indebted to Mr. Hildebrand, of the Shan States, in Upper Burma, for the discovery of this *Dendrobium*, as well as for the introduction of various other good garden-plants—that is, *Lonicera Hildebrandii*, *Aeschynanthus Hildebrandii*, etc. The *Dendrobium* was first introduced to England by Messrs. Low & Co. in 1893, when only a single plant, now in the collection of Baron Schroeder, was received. This week Messrs.

Low & Co. sold a large importation of it by auction, and as the species is known to be a desirable one, and the plants were in good condition, they realized good prices. The species is closely allied to *D. tortile*, which, again, is, of course, not unlike *D. nobile*, but there is considerable variation in color in the new one, some of the flowers being yellowish, others rose-tinted, the lip being blotched with red in some cases, pure yellow in others. The flowers are about two and a half inches wide, and, as in *D. tortile*, the sepals and petals are more or less spirally twisted. It is likely to become a popular plant with Orchid-growers.

DENDROBIUM NOBILE NOBILIUS.—A truly marvelous specimen of this beautiful Orchid was shown last Tuesday by Mr. E. Ashworth, Wilmslow, Cheshire. Some of the pseudo-bulbs, of which there was quite a sheaf, were nearly four feet long, and the number of expanded flowers upon them was three hundred and eighty-nine. Typical *Dendrobium nobile*, when well flowered, is one of the grandest of Orchids, and as the variety *nobilis* is probably the best of the many fine-named varieties of it now in cultivation, the magnificence of Mr. Ashworth's specimen can easily be imagined. The flowers are larger and darker in color than any, the sepals and petals being rich amethyst and the lip dark maroon, with a cream-white margin. There are not a few spurious plants of *nobilis* about, but all the genuine ones are from one plant, which was first shown in flower at Ghent in 1878 by Messrs. Rollison, of Tooting, when it nearly succumbed to exposure, but luckily it was saved by Mr. James, of Norwood, who succeeded in propagating six young plants from the old pseudo-bulbs.

JASMINUM SP. AFF. J. NUDIFLORUM.—Dried specimens of a Jasmine collected in Yun-nan by Mr. W. Hancock, F.L.S., have recently reached Kew, where it has been determined to be a new species allied to *Jasminum nudiflorum*. The latter is one of the oldest and best of our hardy winter-flowering scandent shrubs, its yellow flowers, freely produced in fascicles all along the whip-like branches, being the delight of many an old garden-wall in the depth of winter, if only the sun shines now and then. The new one has flowers exactly like those of *D. nudiflorum*, but at least twice as large, the dried flowers of the former being nearly two inches in diameter. It is to be hoped that living plants of this most desirable plant will soon be forthcoming. Perhaps Dr. Henry, now in England, but who, I believe, intends shortly to return to Yun-nan, will add the introduction of this plant into English gardens to his many achievements in the interests of botany and horticulture. *J. nudiflorum* is a native of China; possibly this new one is a big variety of it. Let us hope it is.

MAGNOLIA CAMPBELLII.—I have already recommended this grand Himalayan Magnolia to readers of *GARDEN AND FOREST*. To-day, Mr. Osborne, the gardener to J. Smith-Barry, Esq., M.P., Fota, near Cork, has sent me two magnificent blooms of it, cut from a tree twenty-five feet high, growing in the open air. He says it is not very free-flowering in the moist, usually sunless climate of Fota, but I have heard of the large specimen in Mr. Crawford's garden, in the same neighborhood, flowering very freely. It is quite hardy at Kew, even the severe weather of the past winter having done it no harm. The flowers are as large as those of *M. grandiflora*, but colored a charming rosy or blush-red, reminding one in their elegance of form and richness of tint of a dark variety of *Nelumbium speciosum*. It is a native of the eastern Himalaya at an altitude of 8,000 to 10,000 feet, where it forms a lofty tree with "white or rose flowers six to ten inches in diameter." The leaves are ovate, glaucous green, about eight inches long and deciduous.

CORNUS MAS.—The prettiest tree in the arboretum at Kew this month is the Cornelian Cherry, a well-known garden plant, but not nearly as plentifully planted here as it deserves to be. The branches are clothed from top to bottom in March with little clusters of small yellow flowers, which glisten in the sunshine and last several weeks. I should place it in the same category among good garden shrubs

or small trees as the Witch Hazel, *Hamamelis arborea*, and if I had a large bank side which I wanted to cover with a deciduous little tree that would produce a beautiful effect in early spring, I would plant Cornelian Cherry in preference to all others. I am not aware if it is largely grown in the gardens of the United States, but I should say it is hardy enough for the neighborhood of New York. It is a native of many parts of Europe and northern Asia. Its fruits are about the size and shape of olives, and cornelian in color. The beautiful American *C. florida* cannot be made to flower in this country.

London.

W. Watson.

New or Little-known Plants.

Echinocactus Wislizeni and some Related Species.

THIS fine large Cactus was first described by Dr. Engelmann in 1846. Since its discovery it has been one of the favorite Echinocacti in cultivation. It is by far the most abundant species of this genus in southern Arizona, and probably reaches its greatest development on the Tucson plains and adjacent foothills. So far as its distribution in Arizona is concerned, it is confined to the south-eastern portion of the territory, with the Tucson Mountains as its western limit. Its northern limit seems to be as marked as its western. Some forty miles north of Tucson it entirely disappears, and its place there and to the west is taken by *E. Le Contii*. It extends eastward through southern New Mexico into western Texas, and southward far into Sonora. This plant has been reported from much farther north than the range here given, but my observations for the past three years draw me to the conclusion that in such cases it has been confused with other species.

Echinocactus Le Contii was first described as a distinct species, but later placed as a variety of *E. Wislizeni*. There is no question but these plants are specifically distinct. The former is the characteristic Echinocactus from the mountains north and east of Phoenix to Yuma, occupying the valleys of the Salt and Gila Rivers and adjacent foothills. It differs from the latter in being usually much more slender and more apt to branch; not infrequently a dozen compact, globose heads form a single plant. *E. Le Contii* is seldom over a foot in diameter, and frequently only from four to six inches. It is usually from one to three feet high. A few specimens south of the Bradshaw Mountains, observed last summer, were nearly six feet in height and eighteen inches in diameter. The flowers appear during June and July, and the fruit begins to mature in August. The flower-buds are brownish-red and usually have an oval or obtuse apex. When fully open, the flowers are yellow. The under sides of the petals are more or less colored with brown and red. The fruit dries on the plant during fall and winter and sometimes remains, held by the dense tangle of spines, for several years. It is longer, narrower and more scaly than in *E. Wislizeni*, and the seeds are slightly larger. In the latter species the flower-buds are acute and the petals are conspicuously streaked with red. The flowers do not appear until August and September, fully two months later than in the previous species. The fruit ripens in November and December and forms a bright yellow crown, which stands out in marked contrast to the deep green stem. The somewhat flattened oval fruit is frequently two inches in length and a little more than half as wide. It is always crowned by the withered remains of the flower. It remains attached to the plant without drying throughout the winter and late into spring.

One who sees these two plants in the field would never mistake them as belonging to the same species. As early as April the apex of *Echinocactus Le Contii* is a dense tangle of numerous red pubescent, twisted, nearly mature spines. At this time the apex of *E. Wislizeni* is nearly free, the spines of the new growth being a half-inch or less in length.

Some miles east of Phoenix, at the eastern limit of the

range of *Echinocactus Le Contii*, and north of that *E. Wislizeni*, is found another large species of this interesting group, namely, *E. Thurberi*. This plant ranges from here along the headwaters of the Salt and Gila Rivers into New Mexico. It is much more of a mountain plant than either of the above-mentioned species.

An interesting plant grows north of Tucson, on the foothills of the Santa Catalina Mountains. I refer to a variety of *Echinocactus Wislizeni** (see fig. 24, page 155). The plant from which the description is drawn was collected some three years ago, and is now growing in the Cactus garden at the University. It resembles *E. Wislizeni* in the season of flowering and ripening its fruit and in the arrangement of the spines. Its golden-yellow flowers and white spines against the green stem make it one of the most beautiful Echinocacti with which I am familiar.

All of these species are known indiscriminately among the Mexicans as Bisnaga. Americans know them as "Nigger-heads" and "Barrel Cacti." They are all great, heavy plants, with strong, hard spines. *Echinocactus Wislizeni* sometimes grows to a height of seven or eight feet, and reaches a diameter of more than twenty-seven inches. I have observed specimens with as many as forty ribs. All of these plants are very succulent and entirely without a woody skeleton. The long slender roots are few and small, compared to the great weight and size of the plant. In this locality the large plants invariably lean to the south-west. Their weight, small roots and lack of woody skeleton make them very unstable, and they settle over in the direction away from the prevailing wind. The whole interior of the plant is a soft, spongy, white, parenchyma tissue, which is so saturated with sap that it may be squeezed from it by the pressure of the hand. This fact has been woven into the fairy tale that the thirsty traveler lost on the desert may secure, by cutting into this plant, copious draughts of a cool and refreshing drink.

The spongy tissue is used to some extent in making candy and pickles. Its value for such purposes, however, does not depend upon any special flavor or nutritive value in the plant, but rather in that it serves as a body to hold sugar and other materials.

University of Arizona, Tucson.

Plant Notes.

ANDROMEDA MARIANA.—A correspondent makes inquiries whether this plant is worthy of cultivation. Without doubt it is among the best of shrubs, and we can see no reason why it is not more generally planted, except the fact that it is a native plant, and, like many other native plants, has been neglected because it was originally the fashion to plant exotics. It is found along the Atlantic coast southward from Rhode Island in low, wet, sandy places. It is common in the Pine-barrens of New Jersey, and covers large tracts in Long Island. It is from two to four feet high. Its leaves are leathery, shining, oval in shape and deciduous. Its flowers, which appear in clusters from the axillary buds, are pure white, nodding, bell-shaped and of a wax-like texture. Unlike many other Ericaceous plants, it will thrive without being planted in peaty soil, although it grows well in deep loam mixed with peat. It is perfectly hardy. Its leaves remain on the long wand-like branches late in the season, and they often turn to an intense scarlet before they fall.

INGA PULCHERRIMA.—The Ingas are stove evergreens from South America and belong to the natural order Leguminosæ. Many of them have rather unattractive flowers of light pink, but the flowers of this one are a very rich shade of crimson. Mr. G. W. Oliver writes that a specimen of this plant, now in flower in the Washington Botanical Garden, is one of the leading attractions of the collection there. The

* *Echinocactus Wislizeni, albispina*, var. nov. Globose to subcylindrical. Number and arrangement of the spines the same as in the species, differing from them in that they are entirely white. Flowers golden-yellow, with no trace of red on the under surface of the petals, appearing in July and August. Scales of the ovary much more numerous than in the species, and usually overlapping even in the mature fruit.

beauty of the flower lies in the stamens, of which there are something like forty in each one of the twenty flowers which make up a single head. The plant thrives equally well in the temperate house or stove, but when grown in the latter it flowers from two to four weeks earlier. The flowers appear with the new foliage, and the contrast between the two is very pleasing. Every summer the plant should be encouraged to make as much growth as possible, as the flowers are always produced on the previous summer's wood and are grown on peduncles an inch and a half long. The shrub grows to a height of about five feet.

BRUNFELSIA (FRANCISCEA) LATIFOLIA.—Brunfelsias are evergreen shrubs, mostly from Brazil, and many of them have

Fig. 24.—*Echinocactus Wislizenii*, var., growing in the Foothills of the Santa Catalina Mountains, Arizona.—See page 154.

been long in cultivation. They need a warm house without too much sun, and, although they will take abundant water when growing actively, the ground should never be sodden, or the roots will suffer, and it is a long process to restore the plant to health. *B. latifolia* takes rank among very choice stove-shrubs, and healthy plants will be certain to bloom in profusion every spring. The flowers are an inch and a half in diameter, of a dark lavender color as they open, and they change to pure white. When planted in coarse peaty soil with good drainage they need no special care beyond a severe cutting back as they become established, in order to keep them compact—that is, to prevent them from growing into a straggling form.

Cultural Department.

A Test for the Quality of Potatoes.

EVERY one knows how much more palatable some potatoes are than others, and there is quite as marked a difference in their food value as estimated by the amount of nutriment they contain in the form of starch. Professor Goff, of the Wisconsin Experiment Station, has been making some tests with potatoes which are novel and suggestive, and they point the way to a line of investigation which it may be worth while to follow out with careful study. We reproduce, in a somewhat condensed form, Professor Goff's account of his experiments in the *Rural New Yorker*:

In making brine for beef it is an old custom to put a potato in water and stir in salt until the potato floats, and this usually proved a safe test. But if two or more potatoes are put in at the same time, they will rarely come up at once. Even when the potatoes are all of the same variety, and are taken from the same bin, considerable more salt is required to bring up some tubers than others. This means that some tubers have a higher specific gravity than others. Now, starch, the portion of the potato that makes it chiefly valuable for food, is heavier than water; hence the heaviest potatoes contain the most starch, and so have the highest food value. They are also finest for table use, because they have the most farinaceous or mealy quality when cooked.

Here is a pointer for potato epicures. By putting a bushel of potatoes into a barrel which is nearly full of water, and stirring in salt, the tubers of the lowest specific gravity—that is, those poorest in starch—will first come to the top. These may be picked off. By stirring in a little more salt another lot will rise, and thus the bushel may be assorted into several qualities. By rinsing the tubers in clean water as they are taken out, they are uninjured, either for table use or for planting, and it is surprising to one who has not made the test, to discover how great is the difference in the table quality of the lightest and heaviest tubers. The former will be soggy and salvy, while the latter will be flaky and farinaceous.

On discovering this marked difference in the quality of individual tubers of the same variety, the question naturally arose as to its cause. It has often been stated that pronged or knobby tubers are poorer in starch than others. The salt test easily shows this to be true. But some smooth tubers will usually rise as soon as the knobby ones, and it is an interesting fact that these light smooth tubers are often undistinguishable by any external mark from the heaviest ones, and this is true even of tubers that grew in the same hill.

Some years since I set out to discover the cause of this singular variation in the starch content of different tubers. The first suggestion was that it might be due to heredity. Accordingly, a lot of potatoes was assorted into three classes by the salt method, and the tubers showing the highest and lowest specific gravity planted separately. But no appreciable difference appeared in the specific gravity of the crops. The same line of selection followed another year showed no more definite results. The question next arose, whether the variation might not be due to the varying depths at which the tubers grew in the soil, and this appeared to be the true solution. Careful tests with several different varieties, and with different

methods of culture, carried on through two consecutive seasons, showed that the tubers that grew nearest the surface of the soil were lowest in specific gravity; those that grew deepest were highest, and those that grew in the intermediate depth were intermediate in specific gravity. This fact suggested that the temperature of the soil in which the tubers grow, may have an influence upon their specific gravity, and that a comparatively cool temperature favors high specific gravity. In support of this view, it may be added that potatoes grown in level culture averaged higher in specific gravity than those hilled, and tests have shown that level soil usually averages lower in summer temperature than that which is ridged.

Potatoes grown closely in drills were found higher in specific gravity than those grown further apart in hills—the more largely shaded soil of the drill culture being thereby rendered

cooler. The commonly accepted view that potatoes grown in comparatively cool climates are usually of better quality than those grown in warmer climates is supported by these results, and we would expect that mulching Potatoes during the hotter part of the season in the warmer climates would tend to improve the quality of the tubers.

The market value of potatoes should be based on their specific gravity. There is no reason why potatoes containing but twelve per cent. of starch should sell for as much per bushel as those containing twenty per cent.; yet such is the case under the present methods of sale. The latter are worth nearly double the former for food, besides being more desirable in every way. Variations as great as this in the specific gravity of potatoes are not unusual. The salt test admits of very easy and economical application. All that is needed is a large candy jar or other wide-mouthed, capacious glass vessel, a hydrometer, a little salt and a few quarts of clean water. A dozen uninjured tubers may be selected as a sample, washed clean and placed in the standard salt solution, which will at once answer the question as to their average specific gravity and consequent food value. When potatoes are sold on their merits as food, rather than on the amount of bulk that they fill, farmers will have some encouragement to produce tubers that contain starch, rather than those that contain water, and potatoes will be more used for food, because their food value and palatability will be increased.

Notes on Orchids.

Lycaste Skinneri.—This is one of the best-known Orchids, and one of the most satisfactory to grow, being of easy management and semi-terrestrial in habit. There is considerable variation in the flowers, which is quite noticeable when a number of plants are in bloom at the same time. One of the purest of white Orchids is the white form of *Lycaste Skinneri*; from this variety the colors vary to deep crimson through all the intermediate shades. A year ago we had some two dozen plants, but they took up too much room on the side benches, due to the spreading habit of the foliage, and we concluded to put them in baskets and suspend them in the cool greenhouse. The experiment has been a decided success; in fact, the plants seem to do much better than when the roots were confined in pots. The baskets are twelve inches in diameter, and some of these have at this time over fifty open flowers. The blossoms are very durable, owing to their wax-like texture, and the plants are especially suitable for room decoration at this season. To grow *L. Skinneri* well the cool house should be kept at about fifty degrees as a minimum. It is one of the easiest of Orchids to accommodate.

We find that these semi-terrestrial Orchids, *Lycastes* particularly, will take liquid nourishment at frequent intervals if applied in weak doses. Under this treatment bulbs of extra-large size are produced, and these bear from ten to twelve flowers each, and sometimes even more. The white form seems more delicate in constitution and needs a little more warmth and less moisture at the roots, or the bulbs become spotted with disease and are hard to grow out of it. A shady position is best during the season of growth, but in winter, when maturing, we give the plants full sunshine until the flowers commence to open. There is practically no resting period for *L. Skinneri*, or, at least, no continued period for drought at the roots; they should be kept moist at all times, and it is one of the reasons why the plants do not do so well sometimes when grown in pots.

Dendrobium nobile Allanianum.—Of the many well-marked forms of the old *Dendrobium nobile*, a few are conspicuous, especially among the dark ones. After the variety *nobilis*, the variety *Allanianum* is, perhaps, the best, the flowers being of large size, very dark and unique, in having a fine polish over the entire surface of the flower. It is as distinct in its way as *C. villosum* is among Cypripediums. We find it to be a good grower, much better than *D. nobile nobilis* in this respect, a great point in its favor, for it is difficult to grow some of the rarest Dendrobiums into specimens. We have given up the use of wood baskets for Dendrobiums, as this genus resents disturbance at the root more than most Orchids, and it is hard to separate the roots from the wood when it becomes necessary to place the plants in larger receptacles. We use perforated pans and suspend them with wires; it is easy to break a pan and take out the plant. In the *Orchid Review* some time ago one of the best English cultivators advised that nothing but clean sphagnum-moss be used for Dendrobiums, and asked gardeners to give this material a fair trial and report the results. I am in favor of the plan after a year's trial. These plants abhor sour, inert material about the roots, and

this fresh living medium seems to be just what is needed. At the end of a year, or after the resting period, this moss is, of course, dead, and we take a Stott sprayer, removing the cap, and with warm water wash every particle of moss from the roots. If the roots are matted about the pans these are placed inside of larger pans with a few pieces of drainage, and the surfacing of moss added. It is surprising how soon the young roots take possession of this fresh moss. We have plants of *D. nobile* three years old, from an old bulb, that made growths two feet long last summer, and in one instance as many as six leads starting away strong for the present year.

Young plants observed starting away from the upper part of the bulbs of *Dendrobiums* at this season should be taken off now and potted in small pots, and these placed in a basket and suspended in a warm house. It is surprising how soon these make good plants to take the place of older and worn-out ones. At this time care must be taken that no water gets into the young growths on dull days, or they will soon rot off and the plant receive a check. This is especially true of *D. Phalænopsis*. To avoid this trouble we have used nothing but fern-root for potting material; in this instance moss seems to retain too much moisture about the few roots made, and these are very susceptible to overwatering. The best time to repot *D. Phalænopsis* is now; small pans should be used—the smaller the better—and they should be suspended in the warmest position in the East Indian house. Plants of this species imported last fall are starting away finely hung up close to the light, and will flower sooner than those that were obtained some time ago and are well settled down to a regular period of growth.

Horticulture is said to be full of empiricisms, and even one genus of Orchids affords a study in the needs of each species. We often know nothing of the conditions under which they grow naturally, and when we are able to learn something of these conditions it is often impossible to imitate them under artificial means. So we have to grope along as best we may, sometimes stumbling upon a way in which a particular plant may be grown well for a long period.

Caladiums for Outdoor Use.

A BOUT this time it will be in order to look over the bulbs of the fancy-leaved Caladiums which are meant for use out-of-doors this summer. The plan of putting them into pots to start their growth is not a good one, since by this method they sprout very irregularly. The best plan, I find, is to chop up some sphagnum-moss pretty fine and start them in that. If the collection is large a place on the bench should be given them; if small, they can be put in boxes. Put a layer of the sphagnum in the bottom about two inches thick, place the bulbs on this according to their kinds, then with a mixture of equal parts of sphagnum and sand cover the bulbs over evenly to a depth of about two inches. Give a very slight watering, keep the temperature about sixty at night, with a rise of about twenty by day. They will begin to sprout in a very short time.

This is the best time for propagating the desirable kinds; there are several ways of doing this. Before putting them in the sphagnum-moss some people prefer to make incisions in the bulb just inside the resting growths—that is, make an incision in the parent bulb between the lateral growth and the central part of the bulb. Immediately after making the incisions see that they are filled with some finely powdered charcoal, as this tends to prevent decay. After sprouting it will be found that numerous roots have been formed; take care that a sufficient number of these are taken with each piece of the bulb, so as to enable them to take hold of the soil immediately. Another plan, which I find to work well with the stronger-growing varieties, is to allow the leaves to become nearly developed, then, if there are sufficient side-growths to warrant it, break off the central growth close to the bulb; this throws strength into the lateral growths and induces new ones to appear.

The fine-leaved varieties lately sent out are of little or no use for bedding out, as they do not stand the sun sufficiently well, and I may say that these kinds are unsatisfactory for most purposes, as they grow too slowly to make large specimen plants, and are very slow to increase when compared with some of the older kinds. These drawbacks are much to be deplored, as the new Caladiums are exceedingly beautiful, but the fact is they are bred with an eye to producing the most gaudy colors, and it has evidently been forgotten that these colors are produced at the expense of constitution. A few of the kinds I have found best for planting out in summer in the full sun-

shine are Dr. Boisduval, Reine Victoria, Edouard Moreaux, Hookeri, Chantini fulgens, Adolph Adams, Triomphe de l'Exposition, Madame Heine, Madame Alfred Mame, and Schmidzii.
Botanic Garden, Washington, D. C.

G. W. Oliver.

Flowers of the Season.

WHITE flowers are never so effective in the gardens as colored varieties, and the early Snowdrops, even if grown in profusion, leave something to be desired for color. The most effective coloring for several weeks has been supplied by colonies of a Taurian variety of *Scilla Sibirica*, *S. Sibirica Taurica*. One colony of these bright plants closely planted forms a carpet about a yard square, giving an indication of possible effects when largely planted. This *Scilla* has good, broad, light green foliage, and flowers profusely on stems about three inches long. The flowers are lighter-colored, and rather prettier, than those of the ordinary *S. Sibirica*, which has not yet come into flower. It is one of the handsomest of early spring flowers, and regularly appears with me before the Snowdrops are fully in mid-season. Another Squill, *S. Whittallii*, is darker-colored, with narrower leaves, and not as attractive. Asa Gray is said to have stated that a white form might be expected sooner or later among every species of flower. There are white forms of both *S. Sibirica* and *S. bifolia*. The former has not yet arrived here, but *S. bifolia alba* forms a colony of dainty pure white flowers at present. This appears to be a form of *S. bifolia*, and at a glance might be mistaken for a dull *Chionodoxa*, the flowers facing upward on the curved stems, and the leaves being narrow and dark-colored.

There are few brighter flowers than *Chionodoxa Luciliae*, which now enlivens the border. The type of this variety, which has large star-like flowers with bright blue-tipped petals with white eyes, leaves little to be desired as a small border-plant, besides which it may be readily secured without much expenditure of capital. The pink and white forms are flowers of exquisite beauty, but in my garden are not as vigorous in growth or as free-flowering as the type. They have never been found in large numbers in Asia Minor, and are said to not come true from seed, so that they are not plentiful. *C. Cretensis* is also white, or slightly tinted, but the white is impure and the flowers are inferior to those of *C. Luciliae*. *C. Tmolusi* is very much in the way of *C. Luciliae*, but the flowers are darker and the effect of the two is quite different when seen in masses. The large-flowered *C. Alleni* and *grandiflora* seem to require more careful culture than *C. Luciliae* to become effective in the border. Under ordinary cultivation the stems bear only two or three flowers. The red varieties of *C. grandiflora* are of a light purplish-red, but attractive. The smaller bulbous reticulate Irises are mostly out of flower. These, as I have noted before, are all hardy here, with the exception of *I. Histrio*, and flower regularly each season. *I. Bakeriana* is the prettiest of the smaller species of this section, while *I. histrioides* is the largest. These, however, all pale before the gayety of *I. Rosenbachiana*, which, as noted last week in *GARDEN AND FOREST*, is quite the best Iris of the season.

The late winter was a severe test of the hardiness of plants, and it speaks well for the hardiness of the Irises that there are no vacancies among the established plants in my collection of varieties of all sections. About the extent of the damage was the burning of the leaves of a few kinds, like *I. Tingitana* and *I. stylosa*, which are better grown under cover if certainty of flower is desired.

Elizabeth, N. J.

J. N. Gerard.

Plants for Spring Forcing.

WITHIN a few years past the practice of using plants in flower for house decoration in the Easter season has extended largely. Every year a wider variety of plants is forced for this trade, and every year better-grown and more shapely plants are demanded, so that the florists' shops are never so beautiful as they are at this season.

Among plants of comparatively recent introduction the improved form of *Astilbe Japonica*, known as variety *Compacta*, is found valuable for forcing. Its spikes are much more compact than those of the type, the flowers are semi-double and the color is almost pure white. This variety seems to force as readily as the well-known old plant, and it flowers quite as freely, while the blooms are more lasting. A still later introduction has been named *Astilbe Japonica floribunda*, and is claimed to be superior to the variety *Compacta*, but it has not been largely forced in this country as yet, and it is too soon to make comparisons.

The Bottle-brush, *Callistemon speciosa*, has been growing in popularity for two or three years past, and in some localities is much sought for. The bright-colored stamens of its terminal spikes of flowers are very showy. The plant belongs to the Myrtle family, and forces as readily as an Azalea, though a little longer time is required to develop its blossoms. It is preferably propagated by cuttings, and the young plants secured by this method are more floriferous than seedling plants.

Cytisus Andreatanus has also been tested to some extent for spring forcing, but, though its showy flowers are quite freely produced, the plant is somewhat naked in appearance and rather too stiff in outline. One of the Bladder-nuts, *Staphylea Colchica*, although an old plant, is just beginning to find favor in Philadelphia for spring forcing, although it has been put to this use for many years in England. This *Staphylea* bears panicles of white flowers similar to those of the American Bladder-nut, *S. trifolia*, but the plant is more dwarf, and the foliage is divided into five leaflets instead of three.

Single and double Lilacs are both used largely for conservatory decoration in the early spring, shapely plants between two and four feet high being the most satisfactory. Plants grown in pots during the preceding summer have the best roots and are most reliable. The Lilacs used for forcing are usually imported stock, and are generally grafted plants.

Pyrus Japonica has also been forced somewhat of late years, and the flowers are usually much lighter in color than they are on plants naturally grown.

Forsythia suspensa is still another hardy shrub that forces well if lifted in the fall, potted up and stored in a cold frame until it is needed. The Double-flowered Almond is also adapted to this use, and needs the same treatment. *Exochorda grandiflora* is rather too stiff in habit, and not bushy enough when small to make a good pot-plant. But it is forced to some extent. Hardy Rhododendrons and Ghent Azaleas can be brought into flower with as little trouble as the Indian Azaleas. But the Ghent Azaleas lack foliage, since the flower-buds grow much faster than the leaves when the plants are forced into bloom. Various shrubby Spiræas and Deutzias are used here, and they generally submit with grace to the forcing process, and all are beautiful in flower.

Some Acacias, notably *A. Drummondii*, *A. Riceana* and *A. armata*, are now found in the stock of all well-equipped establishments, and, though not new plants, are sufficiently uncommon to be genuine novelties to many buyers, and it is said that they have been sold as novelties by some dealers.

W. H. Taftlin.
Holmesburg, Pa.

[In addition to the plants named above, many others have been forced into bloom for the Easter trade in this city. Tree Paeonias, carrying two or three large flowers, are very showy. The Japanese Snowball is also effective as a pot-plant. Mountain Laurel, *Kalmia*, is quite abundant. The beautiful native *Andromeda speciosa*, as well as *A. Japonica*, are also offered, but are uncommon.—ED.]

Thinning Grapes.

IN the indoor grapyery thinning out of the berries is always more or less necessary, according to the variety of the Grapes, as some varieties mature much larger berries than others and, therefore, require more space. The most convenient stage of growth for thinning the bunches varies also according to the variety. Black Hamburg, Barbarossa and similar varieties which set freely, require to be taken at a smaller stage than those varieties which are more shy in setting, as the Muscat varieties. It is not advisable, however, to take them too small, as the berries which are going to stone cannot be determined from those which are not. If the clusters are neglected too long and become overcrowded, the thinning is difficult to perform. The bunches should never be touched with the hand as sweat from the fingers causes rust and disfigurement of the berries, and also impairs the bloom, which begins to form at an early stage. It will often be found necessary to raise the bunch or turn it around a little to get at it conveniently with the scissors, and this can best be done by means of a small piece of wood cut something in the shape of a pencil, but more gradually tapering to one end. This will also be found useful to steady the bunch when required. Thinning is practiced not only to enlarge the berries, but also to produce as large bunches as possible. Each bunch is divided into several small clusters, and the terminal berries on each of these should, if possible, be left and the inner ones thinned out; just enough of the latter being left to fill up the centre, so that the bunch, when matured, will remain compact when cut and laid on its side. If too severely thinned out in

the centre the bunch would fall flat when placed in a dish, which would greatly spoil its appearance for table use. All fair-sized bunches should have the shoulders tied up a little, and with large bunches it is often advisable to tie up several of the upper divisions. This allows the berries room to swell without being thinned out so severely. Grapes intended for winter use require more thinning than those to be used early, or they are apt to damp off in the centre of the bunch.

Tarrytown, N. Y.

William Scott.

The Vegetable Garden.

IN this latitude work in the vegetable garden is backward. Our first sowing of Peas was not made until April 6th, more than three weeks later than the earliest sowing last year. But there is too often undue hurry about getting seed into the ground as soon as frost breaks and before the soil has become sufficiently warm and dry. Sometimes a gardener takes pride in getting his seed in before his neighbors do, but those who wait until the ground works freely have the best garden in the end. We have now made sowings of Spinach, Carrots, Turnips, Beets, Parsnips, Salsify and Onions. We shall make a second sowing of Peas about the 20th of April, using Maclean's Advancer, Shropshire Hero and Juno. Champion of England, Stratagem and Telephone for the main and late crops are sown early in May. The middle of May is soon enough for Bush Beans, but for early picking we work in some well-decayed manure where the Violets are done blooming in cold frames, and plant one or two sashes with Early Mohawk about the 15th of April. In this way we get beans a month ahead of the first outdoor plants.

Onions in flats, under glass, should now be well hardened and ready to plant out. They produce much finer bulbs than when sown outside in the ordinary way. They ought to have rather more growing space, some eighteen inches between the rows and six inches between plants. Beets can be transplanted in the same way, but being more susceptible to injury from frost they should not be set out before May. Lettuce raised in frames can be planted out at once, and sowings of Lettuce and Radishes made at short intervals. Shallots and Garlic should be planted without delay. Leeks are not sufficiently appreciated, as they are much superior to onions for soups on account of their more delicate and milder flavor; they are easily cultivated and stand the most severe winter without injury. In the north of England and south of Scotland many people of the working class pay special attention to this vegetable and grow marvelously fine specimens, and the competition in the numerous vegetable shows is very keen. Seeds started now will give leeks before winter. They should be planted in trenches containing plenty of well-rotted manure and treated liberally like Celery. The finest variety we have grown is the Lyon; other standard sorts are Musselburgh and Giant Carentan.

Early Celery should now be pricked off in boxes and kept growing in a warm house. Before it becomes crowded we transfer ours to frames, planting some six inches apart each way. A little warm manure below the compost will give the plants a good start. Succession sowings for winter use can now be made. For this purpose we find Giant Pascal and Kalamazoo the most satisfactory. We tried a trench of the last named during the past year, and it kept in good condition until the middle of March. Egg-plants and Peppers, when large enough to handle should be pricked off, and Tomatoes for the main outdoor crop should be handled before they become crowded and spindling. For an early crop the plants should be grown singly in pots and staked up securely. They must not be allowed to get pot-bound and take on a yellowish color. Tomatoes fruiting under glass will now require abundant waterings. With the increasing sunlight artificial pollination may now be dispensed with. Liquid-manure, applied twice a week, and a surface-dressing of sheep-manure or some chemical fertilizer in addition, will suit pot-grown plants; lateral roots will require removing weekly, and some of the leaves shortened to admit light to the fruit.

Cabbage-plants should be well hardened before they are set out, and we find it risky to plant out Cauliflowers before May 1st. The plants grown in frames will need plenty of water and liquid stimulants to keep up free growth. Brussels Sprouts are the most useful of the Brassica family for winter, and the fact that large quantities are imported annually from Europe would indicate that more of these should be grown to supply the demands in the large cities. Many worthless strains of this vegetable are on the market, and it seems to be difficult to secure a reliable strain. It is very annoying to raise a good bed of these plants and find that not over one in twenty is worth

the space it occupies. Sutton's Exhibition and Aigburth are excellent sorts if they can be procured true to name, and now is a good time to make a sowing.

Melons and Cucumbers for an early outdoor crop can now be started in pieces of turf or in four-inch pots, thinning the plants out to four or five in each. Cucumbers in hot-beds require copious supplies of water in clear weather. The frames should be closed early in the afternoon after watering; the fruit will swell quicker if the blossoms are artificially pollinated. Lettuce, Parsley, Beet, Carrot and any other crops in frames should have abundant ventilation whenever the weather permits it, and the surface soil should be stirred occasionally, and the sashes removed whenever there is a warm rain.

Taunton, Mass.

W. N. Craig.

Bulbocodium vernum.—In warm, sunny spots this plant, the Spring Meadow Saffron, has been blooming for a fortnight or more. A native of southern Europe, it has long been in cultivation, but it is not generally planted in this country. The flowers are about four inches long, of a bright rosy purple when in bud, which changes to a somewhat lighter shade on full expansion. The plant associates admirably with the Crocuses and Snowdrops, adding a new and distinct color. It

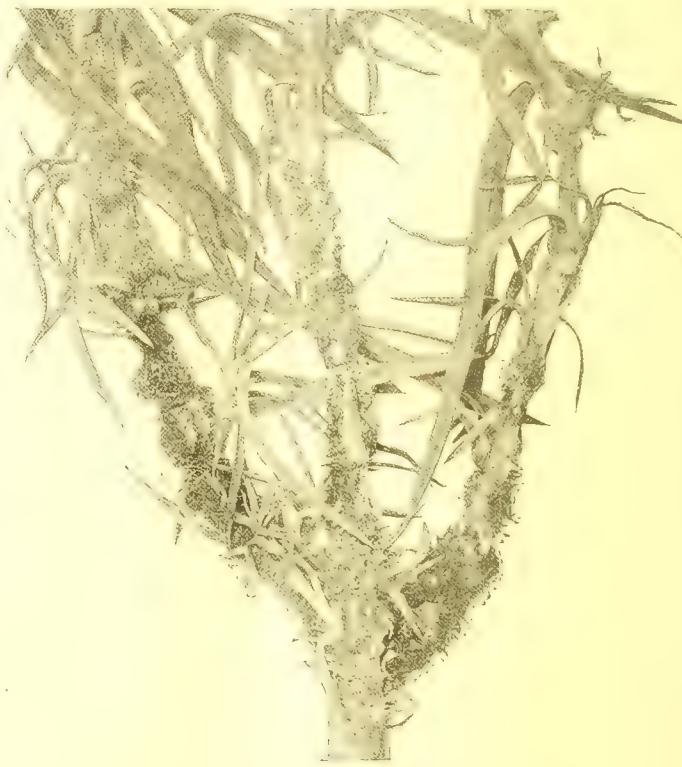

Fig. 25.—Carnation Plant with Aerial Roots.

is perfectly hardy, and, when once established, should not be disturbed for several years, since it is, like many of this class of plants, most effective when grown in masses. It should have the same treatment as the Crocus or Snowdrop. There is a variety with variegated foliage which is not desirable.

Aërial Roots of Carnations.

To the Editor of GARDEN AND FOREST:

Sir,—Samples of strange-looking Carnation-plants have been sent to this station, with queries as to the nature of the trouble and the remedy for the same. At first sight the stems seemed to be covered with a peculiar dark growth unlike that of any fungus known to me. A further inspection showed that the stems had pushed multitudes of small roots (see fig. 25, on this page), which stood close together, and had turned dark brown in color, due to the growth of a black mold—*Macrosporium*, sp.

The precise reason for this peculiar development of roots along the stems cannot be stated, but since the plants had been watered frequently in excess it is not improbable that the formation of the roots was a result of this surplus of moisture.

As only about two dozen plants in a house of ordinary size behaved this way, it is likely that some plants have a greater tendency to throw roots than others or were more favorably situated, or both.

Byron D. Halsted.

The Preparation of Bordeaux Mixture.

To the Editor of GARDEN AND FOREST:

Sir.—The Patrigeon method of preparing the Bordeaux mixture was first published in the spring of 1890.* The directions were to add the milk of lime to a solution of copper sulphate until a twenty per cent. solution of the ferrocyanide of potassium would show no discoloration when added to the mixture. This process soon became known in America, and we find the following directions for preparing the fungicide:†

"The copper sulphate is weighed and mixed with an amount of water sufficient to dissolve it. When it is completely dissolved, the lime, in the form of thin whitewash, is strained through burlap (gunny sacking) into the copper sulphate solution. A drop or two of potassium ferrocyanide (saturated aqueous solution) added from time to time, after thoroughly stirring the mixture, will show when enough lime has been added to form the Bordeaux mixture. If not enough lime has been used the drop of ferrocyanide will turn to a very dark color the moment it touches the mixture; if enough lime has been used the ferrocyanide will not change color when it is dropped into the mixture."

The substance of the above extract was repeatedly published, and it appeared as late as the summer of 1894.‡ Users of the test have been at the same time cautioned to use a sufficient amount of lime, since an excess would do no harm to foliage. But in no case has it been advised to add an excess of lime, the amount called for by the test being sufficient, provided the preparation was well stirred and the proper care exercised in the use of the test. Yet in the fall of 1894 we find that the original formula is no longer unconditionally recommended, but that "a little more lime should be added after this test shows no color," in order that there may be no doubt that enough shall be present.§

The question now arises, why is lime added to the Bordeaux mixture after the immediate demands of the ferrocyanide test have been satisfied? The following considerations may help us to find the correct answer:

(1) When the milk of lime is added to a solution of copper sulphate, the latter is broken up and new compounds are formed. The lime is not added merely to neutralize the acidity of the solution, but a sufficient amount should be present to satisfy all chemical changes. But all these changes do not appear to take place at once; "so it occasionally happens that after the mixture has been standing a few minutes the potassium ferrocyanide will again give the dark color, showing that not enough lime had been added."|| It is an undisputed question that a sufficient amount of lime must be added to prevent any of the copper sulphate from remaining in solution, otherwise the foliage of nearly all plants will sustain injury. Yet the Bordeaux mixture, when prepared according to the original directions of Patrigeon, is not supposed to contain an excess of lime; in fact, the value of the test rests in its power to detect just when no more lime is needed.

(2) That foliage is occasionally injured by the Bordeaux mixture when prepared with the minimum amount of lime cannot be doubted, for injury has followed the use of the mixture when it contained considerable quantities in excess. No definite experiments appear thus far to have been made for the purpose of comparing the action of the Bordeaux mixture when prepared with the ferrocyanide test, and that made in accordance with the commonly accepted formulas. Fairchild, who has made a special study of the Bordeaux mixture, was in doubt regarding the advisability of accepting Patrigeon's method without further experimentation. He says:¶ "It is possible, also, that pathologists have proceeded too rapidly in recommending the use of potassium ferrocyanide in the preparation of this mixture. It has not yet been definitely settled that the mixture, when prepared according to this method, will not contain the basic sulphates and occasionally prove injurious. In attempting to avoid the inconvenience in the preparation of Bordeaux mixture the greatest care must be taken that its real value is not impaired. The excess of lime in the mixture, instead of being an injurious element, may

prove beneficial, preventing injuries from the copper salt, and in other ways being of advantage." Professor Bailey, after extended observation throughout this state during the past season, has come to the following conclusion: "This test indicates when sufficient lime has been added to correct the present injurious effects of the sulphate of copper; but in wet seasons—if, in fact, not in all seasons—an extra amount of lime may be needed to neutralize subsequent changes in the compound. I am strongly of the opinion that the regular formula for the Bordeaux mixture . . . is the safest and best one." My own experience has shown that the most serious cases of the rusting of apples have been in orchards treated with the Bordeaux mixture, prepared with the aid of the test, the applications having been made in orchards about Ithaca, and also in the western part of the state. At Ithaca we had orchards containing the same varieties for comparison, the one having been sprayed with Patrigeon's Bordeaux mixture, the other with that made according to a formula. No definite data can be given, but the impression received from the examination of the two orchards was unfavorable to the use of the test; so much so that a considerable excess of lime was added when the mixture was prepared the second time.

(3) The chemistry of the Bordeaux mixture, as now understood, indicates that more lime is necessary than the ferrocyanide of potassium test demands. Abundant experimentation has shown that the carbonic acid found in rain and dew exerts a solvent action upon the copper compounds found in the mixture whenever no excess of lime is present. In other words, the greater the excess of lime in the Bordeaux mixture, the more slowly will the copper compounds be dissolved, and, therefore, the smaller the excess the more quickly will the copper enter into solution. The solvent action of the water is greater where there is much dew or where the rainfall is more or less continuous. Light rains and a moist atmosphere will dissolve the copper most readily, and the solution will collect upon the foliage unless the rainfall is sufficiently violent to wash it off. Which form of the copper is most readily dissolved from the mixture is uncertain, but Willard has suggested that the solution contains considerable quantities of the sulphate of copper, a compound which is known to be caustic to foliage.† Such conditions very readily explain the injury done by the Bordeaux mixture in 1894, and also the increased injury following the adoption of Patrigeon's method of making it.

(4) The Bordeaux mixture is now frequently applied with Paris green or London purple. These poisons are unsafe to apply to the foliage of many plants unless lime is added to the liquid. But if the Bordeaux mixture does not contain an excess of lime, injury may follow the application of such a combination, especially in a wet season. When Patrigeon's method is recommended, special direction should be given for cases in which arsenites are to be used with the fungicide.

(5) A serious objection to relying upon the ferrocyanide test is the danger arising from its improper use. This was clearly shown in the article of Professor Beach on page 128 of the current volume of GARDEN AND FOREST. Serious injury may follow, and appears to have followed, from such mistakes. When a definite formula is employed there is less liability of error, and, to my knowledge, no preparation has proved itself safer, when the proper ingredients are used, than the formula given below.

Color tests possess a decided value in the preparation of the Bordeaux mixture, since they mark a certain stage in the preparation of the compound. The color of the mixture itself also shows the same. I have frequently made this fungicide without the aid of scales or of the ferrocyanide test, basing the amount of lime added upon the color of the mixture. The use of the test is safer, however, and if a sufficient excess of lime is added the preparation must be as effectual and as safe as if the ingredients had been weighed. But this excess of lime is an uncertain quantity, and as a general recommendation I should prefer six pounds of copper sulphate, four pounds of quicklime and forty to fifty gallons of water as the safest proportions. I have used the formula for three years, partly because the fungicide was used in experimental work and a definite compound was desired; in other cases the ferrocyanide test or the color test of the mixture served as a guide to the proper amount of lime. During this time I have not once strained either the lime or the Bordeaux mixture, since in making the application no trouble was experienced from the clogging of machinery. The McGowen nozzle has been used almost exclusively. With the Vermorel nozzle it may be advisable to strain the lime in the majority of cases, although not necessarily more because the latter is weighed. The weigh-

Notes.

Perhaps it ought to be stated that it is Professor Tuomey himself whose portrait is given with that of the Cactus on p. 155.

Professor Halsted writes that the late winter has been very trying upon the English Ivy which covers many of the older buildings in New Brunswick, New Jersey. The leaves are mostly brown, many of them dead and have the appearance of having been scorched by fire. It may be that the plants will revive with warm weather, but these old vines, which have been the pride of the city, are just now anything but attractive.

It is a well-known fact that many varieties of tree fruits which in the extreme north would perish in a hard winter if root-grafted, can be grown successfully if top-grafted on very hardy varieties. Dr. Hoskins finds that the Sops of Wine Apple is a common failure with him when root-grafted, but when grafted on the Peach Apple it endures the winters perfectly, and has borne profusely for many years, though here and there a limb has died and been removed.

Winter cabbage, which was very cheap until recently, now brings twenty cents a head, a price as high as that asked for new Florida cabbage. New string-beans cost thirty-five cents a quart, and \$1.25 a half-peck is asked for peas. Large bunches of asparagus bring fifty cents. Romaine lettuce from Bermuda costs fifteen cents, chervil ten cents for a small bunch and dandelion fifteen cents a quart. Small heads of hot-house cauliflower may be had for forty and fifty cents apiece, and cucumbers grown under glass cost eighteen cents each.

Professor Jordan, of the Maine Agricultural Experiment Station, has been making some tests which show the folly of growing the large southern Corn in the northern parts of the country to be cut for fodder or for ensilage. This tall-growing Dent Corn makes a great bulk, but the season is not long enough to allow it to ripen. When it is cut in an immature state analysis shows that the Maine Flint Corn, which matures perfectly, is worth more than the southern Corn, pound for pound, judging simply by the per cent. of dry matter. It is also shown that the quantity of dry matter in an acre of Corn at maturity was two and a half times greater than it was at the silk period thirty-seven days before, and that the starch and sugars, which are the most valuable compounds, increase more rapidly than the less important constituents, so that the mature plant is of better quality than at any previous stage of growth.

Owing to the universal observance of Holy Week in the West Indies no pineapples have been received here for almost a week, though nearly five thousand barrels are expected within the next few days. The ripening of this fruit in Cuba has been retarded by dry weather, and the crop is estimated to be twenty-five to thirty per cent. less than that of last season. Prices now are somewhat higher than a year ago, but it is expected will be considerably lower in a fortnight, when the season will be fairly opened. The stock of California Navel oranges of the choicest brands is about exhausted, and a carload of good fruit sold here at auction on Monday averaged at wholesale the high price of \$3.27 a box. Northern Spy and the brighter Ben Davis are the showiest apples now in our markets, and high grades of these command \$6.00 a barrel at wholesale. Strawberries are comparatively plentiful in supply, and well-ripened fruit of good size may be had for forty cents a quart.

When we think of the teeming population which now fills many portions of our country west of the Rocky Mountains, and remember how famous, all over the world, is their singular beauty, and their incomparable value to the tourist, the health-seeker, the agriculturist and the horticulturist, as well as the miner, it is interesting to read what so intelligent a statesman as Daniel Webster thought of them just fifty years ago, and to know that his views were shared by many other prominent public men of the time. In a speech delivered in the United States Senate in 1844, with regard to the proposal that a mail service should be established between Missouri and the Pacific coast, Webster said: "What do we want with this vast, worthless area, this region of savages and wild beasts, of deserts, of shifting sands and whirlwinds of dust, of cactus and prairie-dogs? To what use could we ever hope to put these great deserts, or these endless mountain ranges, impenetrable, and covered to their bases with eternal snow? What can we ever hope to do with the western coast, a coast of three thousand miles, rock-bound, cheerless and uninviting, with

not a harbor on it? What use have we for such a country? Mr. President, I will never vote one cent from the public treasury to place the Pacific coast one inch nearer Boston than it is to-day."

The tendency to use plants in flower for house and church decoration at Easter was stronger this year than ever, and was conspicuously manifested in the increased size of the specimens offered. Of course, there was a great array of Lilies, and plants were valued according to the number of flowers they carried, each flower being valued at twenty-five cents. Sometimes several bulbs had been grown in one receptacle, and these masses, when exceptionally well-flowered, often commanded, with the fancy baskets in which they stood, \$10.00. There were Dutch bulbous plants, Hyacinths, Tulips and Daffodils, in abundance; Violets and Cyclamens in pots, and Astilbe in great quantities, including some of the newer varieties under various names, all very beautiful, but none of them superior to the type, which, after all, has an airy grace which the more compactly flowered plants do not possess. Among many other shrubs forced into bloom, Hydrangeas, Cytisus and Azaleas were far the most numerous. Fine Hydrangeas, with ten or a dozen heads of flowers, often commanded \$10.00. Trim little well-flowered plants of Cytisus could be had for \$2.00, and larger ones, the price rapidly increasing with the size, cost \$30.00, and even \$50.00. Plants of this last grade had stems two inches in diameter and were six feet high and nearly as much across. The Azaleas sold for \$4.00 for well-flowered plants a foot across, to \$100 for densely flowered specimens five feet and more in diameter, and there is a story of an exceptionally large and well-flowered plant, some eight feet in diameter, which sold for \$500. Singularly beautiful plants of Acacia paradoxa commanded \$50.00. The clear yellow of these flowers and the deep green of the leaves made this altogether the most pleasing and showy of the yellow-flowering plants. Among the other flowering shrubs, specimens of the tree Paeony, Reine Elizabeth, were very effective. Our native Laurel, Kalmia latifolia, Andromeda speciosa and A. Japonica, Lilacs, Snowballs, Boronias, Metrosideros were more rarely seen, and the price for these varied according to their quality and size.

The fungus which spots the leaves of the Quince and produces the black spot on the fruit is nearly always present, and this is especially true when the trees are standing in sod. It is from the effect of this disease that the leaves of the Quince often begin to fall in August and in early September, while, of course, the foliage ought to persist until the fruit has ripened, for the loss of the leaves deprives the fruits of nourishment at the time when they are completing their growth. When the leaves die before their time the fruit remains small and immature. This defoliation also prevents the tree from storing up energy for the next year's crop. But not only is the fruit stunted before it is fully grown, but the fungus also attacks the fruit itself, causing cracks and lop-sided growth, as in the case of pears when attacked by the same fungus, *Entomosporium maculatum*. In a late bulletin on the Quince in western New York, Professor Bailey gives the results of experiments to show that this fungus can be held at bay by spraying with the useful Bordeaux mixture. On the 25th of June, last year, when the leaves in a Quince orchard had been already badly marked, this mixture was sprayed on so abundantly that all the foliage and limbs appeared deep blue when the application had dried. It was repeated on the 9th of July, when, although the disease did not appear to have progressed much, the foliage remained equally blighted in the sprayed and unsprayed portions of the orchard, and the fruit upon the sprayed portions was browned and discolored by the treatment. The experiments seemed so unpromising that nothing further was done, but on the 21st of September a visit to the orchard showed that the fruits on the sprayed rows were twice as large as those on the untreated rows. They were yellower, less fuzzy, uniform in size, and the russet discoloration had all gone. Half of the foliage had fallen from the unsprayed trees, and the remaining leaves were small and yellow. The foliage on the sprayed trees was large and dark green and plainly helping the growth of the fruit. Professor Bailey accounts for the fact that the sprayed fruits were less fuzzy than the other ones by supposing that this woolly covering, which is a living growth on the surface of the fruit, was killed by something in the application. The so-called moss, which is really one or more species of lichen which had overgrown the trunks of many trees, was also completely destroyed. Experience seems to show that the spread of the spot may be wholly checked, even after the leaves are conspicuously marked by it. Of course, it is unwise to wait until the disease appears, and the first application ought to be made soon after the blossoms fall.

Magnolias as Garden Plants.

THE illustration on page 165 of this issue, made from a photograph of a tree in Mr. Hunnewell's garden at Wellesley, in eastern Massachusetts, shows that this southern plant is capable of flourishing in regions of far greater cold than that which usually prevails in its native home. Of all the Magnolias, a genus celebrated for its large and handsome flowers and large leaves, this species produces the largest flowers and leaves, and the flowers and leaves of no other inhabitant of extra-tropical forests equal them in size.

Magnolia macrophylla is a stately tree, with horizontal wide-spreading branches, and in its native forests sometimes attains a height of fifty feet and produces a trunk eighteen or twenty inches in diameter. The leaves, which are clustered at the ends of the stout branches, are bright light green on the upper surface and silvery white on the lower, often thirty inches long and nine or ten inches broad, and form a splendid setting to the creamy-white fragrant flowers which, when fully expanded, are often twelve inches in diameter. Photographs or words cannot express the beauty of one of these trees when it is in bloom, or convey any idea of the solemnity of the great flowers, which one cannot contemplate without a feeling of reverence and awe and a sense of wonder that Nature in her wisdom and for some good purpose has placed in our forests of Oaks and Pines such a marvel of rich and gorgeous beauty.

Magnolia macrophylla belongs to a region of luxuriant and varied forest-growth, its home being at the base of the southern Alleghany Mountains, where it is distributed from western North Carolina and south-eastern Kentucky to middle and western Florida and southern Alabama, extending also through northern Mississippi and inhabiting central Arkansas. Known only in a few widely separated stations in the Atlantic states, this tree is more abundant west of the Alleghany Mountains, and seems to grow to its largest size in some sheltered limestone valleys of northern Alabama. Protection from the wind is essential to it, as its great delicate leaves are easily torn to pieces and de-

stroyed by the wind, and it is always found in small groves in forest-glades or little valleys, surrounded and often overshadowed by Swamp Chestnut Oaks, Dogwoods, Hickories and Gum-trees. It is a century since the elder Michaux, the French botanist and traveler who explored eastern North America under the auspices of the French Government, discovered this tree near the town of Charlotte, in North Carolina, but it has never been much cultivated or become very well known in gardens. That it is not more often seen in those of the northern states is certainly surprising, for, after its first years when young plants are better for a little protection, it is very hardy and begins to flower when only a few years old. In Europe, especially in England, Magnolia macrophylla feels the want of the hot summers and dry autumns of eastern America to ripen its wood, and, like many other North American trees, does not flower satisfactorily. This is true of most other Magnolias, which, as a general rule, are more satisfactory garden plants in the eastern United States and in China and Japan than in other parts of the world—a fact that is explained by the distribution of the genus which is now chiefly confined to eastern America and eastern Asia, although four species extend into the forests of the tropical eastern Himalaya.

Twenty Magnolias are known, although it is not improbable that others will yet be found in the almost unexplored forests that cover the mountains of south-western China, where trees of various genera abound and where one species of Magnolia is already known.

The Magnolias can be grouped into two sections. Those of the first section produce flowers before the appearance of the leaves, while in those of the second section the flowers do not open until after the leaves have grown to their full size. All the American Magnolias belong to the second of these sections, the species with precocious flowers being confined to Japan, China and India. To this section belong the Chinese Yulan Magnolia, Magnolia conspicua, and its various hybrids and varieties; Magnolia Kobus, a large tree of northern Japan; Magnolia salicifolia, of northern Hondo, a small shrubby tree with fragrant foliage, recently introduced into cultivation; the shrubby Magnolia stellata, and Magnolia Campbellii, of Sikkim, a stately tree with rose-colored or pink flowers. This tree, which, unfortunately, is not hardy in the northern states, has produced flowers in southern Ireland, and it may possibly thrive in our southern states, where its cultivation certainly should be attempted.

Of exotic species of the first section Magnolia hypoleuca is best worth cultivating in this country. It is a noble tree, growing sometimes in the forests of Yezo to a height of one hundred feet, with large leaves arranged in whorls at the ends of the branches, and large flowers with white sepals and petals, and prominent cones of bright red carpels. In foliage and flowers Magnolia hypoleuca resembles our American Magnolia tripetala, but it is a larger and handsomer tree and much harder in the northern states.

In the great evergreen Magnolia of the southern states the temperate countries of the world have the most beautiful evergreen tree known in gardens. With its smaller but more fragrant flowers and its lustrous leaves, deciduous at the north and persistent at the south, the Swamp Bay, Magnolia glauca, is an ornamental tree of peculiar charm and beauty. These two and Magnolia macrophylla are the most valuable of the American Magnolias among ornamental trees, but the other species have each their peculiar beauty, and Magnolia acuminata is also an important timber-tree.

We have desired, in writing these notes on Magnolias, to call attention to the fact that our climate is specially suited to the cultivation of these trees. All the American species, with the exception of the evergreen Magnolia of the south, are perfectly hardy as far north as eastern New England. Magnolia hypoleuca and Magnolia Kobus are apparently as hardy here as in their native forests of Yezo, and promise to grow here to a large size. Magnolia Watsoni and

Magnolia parviflora, of China, deciduous-leaved species with beautiful, fragrant, cup-shaped flowers, are both hardy here and delightful garden-plants; and all the precocious-flowered Yulan race grow and flourish here with as much freedom as in the gardens of China and Japan, spreading, when all deciduous-leaved trees are still bare of foliage, marvelous clouds of snowy white or purple bloom.

THE contributions to the Parkman memorial, of which we spoke last week, have already been so liberal that the success of the project is put beyond question. It is the desire of the committee, however, that as large a number of people as possible should be allowed to assist in this work. Francis Parkman inspired his readers with feelings akin to personal affection, and all who desire to manifest this sentiment of regard ought to be allowed to help in this commemorative work. Indeed, the committee have reached a point where they would prefer to receive the contribution of a single dollar, if it is given with enthusiasm and affection, rather than a much larger sum from one who subscribes simply to be in the fashion. We repeat that contributions of any amount can be sent to Mr. Henry L. Higginson, 44 State Street, Boston.

Forestry and the Abandoned Farm.

IN the "Descriptive Catalogue of Farms in Massachusetts, abandoned or partially abandoned," issued by the State Board of Agriculture, are descriptions of farms containing considerable land growing up to forests. The woodlands are referred to after this manner, in the list of descriptions of farms: "It is estimated that there are sixty tons of hemlock bark on the place." "Estimated that there are 200,000 feet of lumber on the place." "I think there is \$2,000 worth of wood and timber on the place, principally pine and hemlock." "It is estimated that there are over 2,000 cords of wood on the place."

Believing that in the future, perhaps in my own time, these cheap lands of New England may be valuable as timber preserves, if nothing more, I entered into correspondence with a person who advertised in the catalogue referred to, a property of 330 acres in Berkshire County, on which were 195 acres of woodland. I had simply a forestry investment in mind. Last November, therefore, having occasion to go to New England on other business, I took the opportunity to visit this farm, which is only about twenty-five miles from my birthplace.

The place was owned by a man who is now farming in Kansas. Seven years ago he suddenly packed up his goods and left his old home deserted, and went west. He was prosperous in New England, and left his buildings in good condition. Since then they have been untenanted. This farm was first offered for sale at \$1,200, and the price was gradually reduced to \$700, as no one would buy. There are two houses on it and three barns, one house and two barns being in fair condition. The buildings are located on the summit of a magnificent hill, with a very easy approach, from which is obtained a mountain view of great beauty. The buildings stand in the midst of a large amount of smooth meadow and pasture land. The many acres of grass land are unusually free of stone, and a mowing-machine can be used to advantage over it all.

Back from the pasture and tillable fields, surrounding the entire property, is the forest of various stages of growth. I spent the best part of a day tramping through the woodland and looking into its possibilities. The trees are mainly White Ash, Yellow Birch and Sugar Maple. There is also some Spruce and Hemlock. White Ash predominates, and many trees have a diameter of six inches. The latest clearing on the farm is growing up to Beech. Although not specified in the description, there was an additional wood lot of forty acres, and that was "thrown in" without increasing the price.

This farm of 361 acres, containing over 225 acres of woodland, I bought for \$700, about \$1.90 per acre, in-

cluding five buildings, three of which can be put in good repair with a slight expenditure of money. The woodland, however, was the main consideration. Though believing that this property might at least pay four per cent. on the investment, before buying I discussed the wisdom of such a purchase with two men who ought to be capable advisers. One of these is a well-known farmer in a Massachusetts town, and an old friend of mine, who has had large experience in woodland property in New Hampshire and Massachusetts. He expressed it as his opinion that such woodland would prove a good investment, and stated that he already had bought and was holding some 200 acres of just such property. His advice was to buy by all means. The other person with whom I consulted was the Chief of the Forestry Division of the United States Department of Agriculture, Mr. B. E. Farnow, and his opinion was also favorable to the purchase of the land. There is certainly no great risk involved, inasmuch as one can easily get nearly 1,000 cords of wood from the property now.

Here is a farm, within four miles at its nearest point of a station on the Boston and Albany Railroad, on a decent highway, with a fair set of buildings, with plenty of good arable land and excellent future timber resources, selling at a lower price than land can be bought for anywhere in the west to-day—and this in the very heart of civilization. The scenery gives spacious views of the character well known in Berkshire County. A beautiful mountain lake is only half a mile away. Lenox and Stockbridge are each less than fifteen miles distant.

Why has such a place lain vacant so long? So far as I can ascertain there are only two serious objections against this as a home. First, its isolation; secondly, the snows of winter. The post-office, church and railroad station are four and a half miles away, and it is a mile to the nearest neighbor and the school. In winter the snow accumulates to a great depth, and sometimes it is difficult to travel across country on account of the drifts.

But land can be bought here cheap, and it seems to me that this is a good time to buy these woodlands when so little invested will buy so much. Our forestry problems are receiving more and more attention. Schools of forestry will be established soon, and we shall have trained foresters in America. Notwithstanding the fact that cord wood is cheap in New England to-day, and the demand is weak in places, the value of American timber must increase rather than decrease in future years. It is my purpose to attempt a systematic handling of this woodland in order to ascertain whether an annual source of revenue cannot be derived from it. As New England was the part of our country first denuded of its forests it would seem appropriate that in this region the first attempt should be made to establish a forestry system. It is true that some forest-planting has been done on the sandy shores of Cape Cod, but the rocky hills of western Massachusetts also offer a good field for working out special forestry problems. The State Agricultural College of Massachusetts is already giving increased attention to forestry, and it is safe to assume that the time is not far distant when, with greater facilities for education in forestry, the woodlands of the state will be valued as a perennial source of revenue.

C. S. Plumb.

A Valuable Fruit-tree for the High North.

VAST territories of the North American continent, such as Northern Canada, British Columbia and Alaska, comprising tracts as extensive as several European kingdoms, are outside of the geographical range of the common fruit-trees. No practical method has yet been proposed for the acclimatization of fruit-trees in the high north, and hitherto there has not been much prospect of the discovery of any new fruit-tree especially adapted for these cold regions.

Fortunately, we have a new fruit-tree now which is suited to the gardens of the icy north, a tree that is absolutely hardy and produces unfailing crops of delicious and

fine fruit. It is the first fruit-tree for the coming orchard of the high latitudes. I can write with much confidence about the tree because it has been tried for several seasons in the high latitudes of Europe above the limits of other hardy fruit-trees.

The tree is a form of the Mountain Ash, *Pyrus aucuparia*. The fruit, so far from being acid and rough, has a deliciously sweet-sourish taste, and is twice as large as that of the common type.

Ten years ago, I accidentally saw an account of this new fruit-tree in an Austrian horticultural paper, and in the belief that it would prove a desirable acquisition for the Scandinavian Peninsula, Finland and Russia, where the same cold climate prevails as in the northern countries of the New World, I drew the attention of the Director of the Horticultural Department of the Royal Swedish Academy of Agriculture, Mr. Erik Lindgren, to this valuable novelty and proposed its cultivation. The tree was introduced in Sweden in 1885, and has proved to be absolutely hardy, having ripened its fruit even as far north as Pitea in latitude 66° , where no other fruit-trees can be cultivated.

The home of this fruit-tree is the high mountain region of northern Machren, in Austria. The Mountain Ash is a characteristic tree of the mountains of Machren and also of Schleisen, and appears there in such masses that forests are formed of these trees. About ninety years ago, some boys who were watching cattle near the small village of Peterwald discovered that a certain Mountain Ash in the forest had unusually large and sweet fruit. A farmer, Christof Harmuth, who had some knowledge of horticulture, made an experiment and grafted this form upon a young wildling near his farm. When the grafted tree had grown up and produced fruit, he found, to his satisfaction, that it was even larger and better than that of the mother tree. New grafts from this improved form gave a still finer quality of fruit. The new fruit-tree soon became popular in the neighborhood of Peterwald, and trees were planted on nearly every farm. The climate of Peterwald is very cold. The altitude above the sea is nearly 2,300 feet. Oats and barley can be cultivated only in the valleys, but often before the harvest-time in September the oats are spoiled by the snow. At the altitude of 1,750 feet the common fruit-trees fail to give any regular crops, and at 2,000 feet only a kind of Cherry-tree, *Prunus Avium*, ripens its fruit. Strangely enough, "die süsse Eberesche," or the Sweet Mountain Ash, as the tree is called in Peterwald, has been confined to this small place until quite recently. The real importance of the new fruit was perceived by Mr. Franz Kroetzel in 1885, who described the tree and reported on it, with the result that the Minister of Agriculture paid special sums for two years for the propagation and spreading of the tree among the inhabitants of the high mountain regions of Austria.

In Sweden the tree has been largely distributed by Mr. Lindgren, who, in a report to the Swedish Academy of Agriculture, writes: "During 1892 several young trees of the Mountain Ash have produced plenty of fruit, and I have consequently had better opportunities than during previous years to try it. I consider this fruit-tree as very valuable, especially for the northern provinces, and it should be grown in every district. The fruit, when slightly touched by frost, has a delicious taste. Even persons that are rather particular in matters of taste find this fruit very good. The tree has also a more elegant appearance than the common form, and the wood ripens earlier in the autumn."

The Mountain Ash belongs as an indigenous tree to the very coldest regions of the world, and this variety is undoubtedly as hardy as the type. In Europe the Mountain Ash appears at the North Cape, on the coast of the Arctic Ocean, although there only as a shrub; it is also to be seen in Greenland and in America.

In the United States this fruit-tree will prove a valuable acquisition to many large mining towns in the high altitudes of the Rocky Mountains in Colorado, Nevada, etc. In the small gardens here, where only vegetables and

flowers are now grown, whole orchards may be planted. No improvement of the soil is needed for this fruit-tree, that deserves attention for use even as an ornamental park-tree. The light greenish tint of the leaves is always beautiful, and the white flowers in the spring, as well as the large clusters of brilliant red fruit in the fall, are very attractive. The fruit will serve for the same purpose as the expensive cranberries bought from the east. It can also be used as a preserve, in pies, etc. Served as a dessert fruit it is showy and attractive in glass, and it compares favorably with many other small fruits.

Through continued culture and careful selection, still finer varieties will undoubtedly be obtained from the present form, as has been the case with all other fruits.

The fruits of the Sweet Mountain Ash are almost pear-shaped; the leaves are larger than those of the common Swedish form, the segments longer and narrower.

Botanic Garden, Stockholm, Sweden.

C. V. Hartman.

Bull Pine in the West.

DURING the period of most rapid settlement of the states west of the Mississippi River, the only Pines offered in quantity by the nurserymen were the Scotch, Austrian and White Pines. Of these the two former have been found much better adapted to the greater part of Kansas, Nebraska and the Dakotas than the latter, but it is believed that the Rocky Mountain form of the Bull Pine, *Pinus ponderosa*, Douglas, will prove the most useful species of the genus for planting on the plains, because of its ability to withstand extreme drought. It is a distinctly western species, ranging from the Pacific coast, where it attains its greatest development in Washington and Oregon, to the valley of the Niobrara River, in Nebraska, and South Dakota. For cultivation in the Plains, seeds should be secured from trees on the eastern slopes of the Rocky Mountains, the western form of this, as of many other conifers, not being hardy on this side of the continental divide.

I was especially interested in this species as it grows along the Niobrara River (longitude about $99^{\circ} 45'$), and at Fort Robinson, in north-western Nebraska. Ten miles north of the town of Ainsworth, the Bull Pine is found on the slopes and crests of gulches which break from the high level of the prairie to the Niobrara valley. The soil is an extremely fine, light-colored clay sand, with numerous pockets of almost pure, rather coarse, sand. No rain had fallen for months, but in all the "pockets" facing north the soil is moist within two inches of the surface, even near the crest. The most vigorous trees are found in these pockets, but isolated specimens stand in the driest, most exposed southern slopes. The bottoms of the gulches are filled with deciduous trees, mostly Box Elder and Green Ash. The largest Pines seen were not more than eighteen inches in diameter breast-high, and the tallest tree found measured fifty-five feet high. The gulches are fenced for pasture, and no trees younger than five years were found. A very few Pines were growing on the level prairie, but these were near the crest of the gulch. This shows, however, that if protection from fire and stock could be had, the Bull Pine would seed the ground.

At Fort Robinson this Pine occupies the slopes and crests of the ridges, and even the high buttes, with precipitous sides, support a sturdy growth of the Pine on their tops. A careful examination of the timber reservation at Fort Robinson shows the urgent need of protection against stock and fire. The settlers in the vicinity are permitted to use the reservation as grazing-land. The higher slopes, rising 200 to 400 feet above the valley, are covered with widely spaced Bull Pines in sufficient numbers to insure complete seeding and a close stand if protection could be secured. The soil is a very dry sandy clay, with coarse gravel, and the herbage on the hills is scanty. The growth in this dry region is necessarily slow, and it is to be hoped the reservation, which was established to supply the adjoining fort with fuel, can be thoroughly protected, as it

affords a fine opportunity to test natural reforestation under unfavorable climatic conditions.

The Bull Pine was planted in the Sand Hill experiment referred to in the article on Banksian Pine, but a very poor stand was secured. At Franklin, Nebraska, on the south line of the state (longitude about ninety-nine degrees west), the Bull Pine has been more thoroughly tested than anywhere else in the west. Notwithstanding the unprecedented drought of the past two years in that region, this Pine is vigorous, far surpassing the Scotch and Austrian Pines. I measured two trees that were nine years from the seed which were over eight feet high. The growth of Scotch Pine is somewhat more rapid, but less vigorous. The soil at Franklin is the typical clay loam of the west, and success there, coupled with the northern range of the species, indicates its special fitness for forest purposes throughout, at least, the northern part of the plains.

Charles A. Keffer.

Washington, D. C.

Plant Notes.

DEUTZIA PARVIFLORA.—A correspondent writes that he has seen this plant recommended, but that he does not find it in the catalogues of some of the largest growers of ornamental shrubs. There is no reason why so good a plant should not be generally offered by nurserymen. *Deutzia parviflora* was figured in *GARDEN AND FOREST* as long ago as 1888, and at that time we stated that it had been cultivated for some years in the Arnold Arboretum, having been received from the St. Petersburg Garden. It is one of the most hardy and altogether desirable of Asiatic shrubs which will grow in this climate, and it is the most beautiful of the three or four *Deutzias* which are grown here. A glance at the picture of a flowering branch of this plant in vol. i., page 365, will show that it is altogether different in appearance from the other *Deutzias*. It grows to a height of four or five feet, making a compact bush with brownish yellow bark and dark green elliptical leaves. The flowers are borne in corymbs, and appear in this latitude the last of May or the first of June. They are pure white, and borne in such numbers that they quite cover the upper portions of the stems.

PUSCHKINIA SCILLOIDES, var. COMPACTA.—This charming little plant is now flowering in sheltered places. It is best described as a light blue striped Squill. The groundwork of the petals is white, a pale blue stripe running down the centre and sides of the segments of the perianth. The flowers are borne in spikes on stalks about six inches high, and open with the development of the leaves. In the type the flowers are few in number, but in this variety they are abundant. It is perfectly hardy, and should be planted in masses with Squills and the Chionodoxas. Like these plants, they should be allowed to grow in the same place for several years, at least, not being lifted until they become crowded. It is a native of eastern Europe and western Asia. *Puschkinia libarotica* is a synonym of the type, which is inferior in every way to the variety described.

SCILLA BIFOLIA.—This is one of the early-blooming Scillas or Squills, which is not so common here as *S. Sibirica*. It is a native of southern Europe, is perfectly hardy, and, although not so showy as the better-known *S. Sibirica*, is well worthy of a place in every garden where it is desirable to obtain variety. The flowers are of good size and abundant; they are deep blue, almost purple, and sometimes have a reddish tinge. The leaves appear with the flowers, and are generally two in number, hence the name. They should be planted in masses in well-drained soil in a sunny position, and not lifted and separated until this is necessary. The Dutch Yellow Crocus, now known as the Large Yellow Crocus, a variety of *C. aureus*, opens at the same time with *Scilla bifolia*; the two planted together make a pleasing contrast and a very bright spot in the garden in the cold spring-time.

CHIONODOXA GIGANTEA.—This *Chionodoxa* is of recent introduction. It is probably a variety of *C. Luciliae*, and is

sometimes offered under the name of *C. Luciliae*, var. *grandiflora*. It is, nevertheless, a most distinct plant, well known and recognized by gardeners and dealers in bulbs. The flowers are much larger than those of *C. Luciliae*, and borne on short nodding scapes, two or three in number. The color is a very pale delicate porcelain-blue, somewhat reminding one of the Hyacinth Czar Peter. It is certainly one of the best and most distinct of all the Glories of the Snow, and should be more commonly planted. It is perfectly hardy, and succeeds admirably if cultivated in the same way and in the same beds as ordinary *Chionodoxas* and Squills. It is in bloom now, but is a trifle later in flowering than *C. Luciliae*.

ANEMONE BLANDA.—This lovely little flower, one of the earliest of its class, and much earlier than its relative, our *Hepatica*, is an inhabitant of mountain regions in Syria, Greece and other parts of south-eastern Europe and of south-western Asia. Transplanted to American soil, it thrives remarkably well in suitable situations and is hardier than would be supposed, considering its natural habitat. It is a tuberous-rooted species, sending up slender, short stems three or four or more inches high, bearing much-divided leaves and solitary flowers. These blossoms, expanded, measure from an inch and a half to two inches across and are composed of numerous narrow petals, varying in color from deep blue or a purplish tint to almost white in the different varieties or forms. In mild weather these flowers open in February and March, quite as early as the better-known cheerful yellow-flowering Winter Aconite. The plant requires a good light, warm, well-drained soil, one composed of sand and loam being excellent; a warm sheltered situation or southern exposure, protected from other sides, is the best. A spot that is so hot and dry in summer that scarcely anything will live on it seems more suitable than a moist and richer one. The plants will thrive where there are only three or four inches of soil on top of solid rocks and which in summer often becomes dry and parched. As the leaves ripen and dry off early in the season the roots are dormant in the hot summer months. This species is perfectly hardy without protection in a climate like that at Boston, Massachusetts, where the mercury sometimes falls many degrees below zero of Fahrenheit. In the warm corner of a rockery, on the south side of a house close to the foundation-walls and in other similar situations it will thrive and take care of itself when once established and kept free from encroaching weeds and other plants. The tubers should be planted in the autumn a couple of inches deep. Their increase is usually slow.

HIPPEASTRUM VITTATA SUPERBA.—A remarkable specimen of this plant was exhibited by Mr. H. H. Hunnewell in Horticultural Hall, Boston, two years ago, for which Mr. Harris, his gardener, was awarded a silver medal. It is again in splendid bloom. This variety is one of the best of the older sorts, and enters into the parentage of a large percentage of recent kinds. Mr. Hunnewell's plant carries eighteen scapes almost two feet long, nearly all of which bear four flowers from five and a half to six inches in diameter. The name is due to the red and white stripes running lengthwise through to segments of the perianth. Hippeastrums, or Equestrian Star Lilies, have rapidly increased in popularity during late years. For some reason, until recent years, they have been very expensive and scarcely within the reach of persons of moderate means. There is little need to buy the high-priced varieties when seedlings can be raised so easily. In three places near Boston 600 seedlings were raised last year. The majority of these will probably bloom next winter. Hippeastrums need a resting season, though never to be thoroughly dry, and they flower mostly in April. Growth commences with some kinds early in the winter, and continues slowly. They force easily, and, although their natural season for flowering is April, they can easily be brought into bloom a month earlier.

BORONIA MEGASTIGMA.—This plant, which is now rather largely grown in London for house decoration, is only

Fig. 26.—*Magnolia macrophylla*, at Wellesley, Massachusetts.—See page 161.

found in a few private gardens in the United States, and commercial florists have not yet learned its value; or, perhaps, its rarity here is due to the supposed difficulty of cultivating hard-wooded Australian plants. This Boronia is a delicate-branched shrub with small leaves, divided into from three to five narrow rigid leaflets, and small axillary subglobose flowers, maroon color on the outer surface of the petals and yellow on the inner. The value of the plant is in the delicate and delightful fragrance of the flowers, a small specimen perfuming a whole house. Plants are usually propagated from cuttings of half-ripened wood, which must be carefully watered and shaded, as they are extremely sensitive to bright sunlight or excessive root or atmospheric moisture. Plants may also be raised from seed, which can be obtained from German or Australian seed dealers, large quantities being collected from wild plants in the Australian bush. The most successful cultivators here plant the young plants in the open ground in summer, but are careful to shade them with lath frames from the direct rays of the sun, and in winter grow them in a low temperature, bringing them gradually forward in greater heat when they are wanted to flower. They are planted out again during the second summer, and, after flowering again the following winter or spring, when the plants should be about two feet high and as much through, they are thrown away and replaced by younger specimens. A plant placed in an ordinary living-room when the flowers are opening should remain in good condition for two or three weeks, filling it with a delicate fragrant odor which is slightly pungent, like that of most other flowers of the Rue family, to which Boronia belongs. London florists find their profit in selling bushy well-flowered two-year-old plants for five shillings each, and in this country many people, if they once knew this Boronia, would gladly pay two or three times five shillings for equally good plants.

Cultural Department.

Flower Garden Notes.

THE unusually late spring makes garden work a week or two later than in ordinary seasons. Though planting cannot be done now, the preparation of the soil can go on, and when herbaceous plants show signs of activity changes can then be quickly made. The delay caused by the late spring enforces what has been advised before—that fall planting is always preferable for this class of plants, since in most cases one can judge better of the habits and height while the tops are on the plants. We find each year that some kinds will outdo themselves in vigor, and need to be moved further back, divided or thinned. If there is doubt now as to how the alterations should be carried out it is better to wait until another year, and make careful note during the growing period, so that the necessary changes may be made in the fall.

The planting of shrubs and conifers should be done now if they have already been lifted to prevent an early start of the buds. If this provision has been taken there need be no risk in planting until a month later. When planting is well done it is done for all time, and it is best to have the ground well dug at least eighteen inches deep. This can be accomplished by trenching or double digging the soil and mixing the manure well into the bottom, for if the roots are encouraged to go well down there is much less danger of injury from drought in hot weather; besides, trees and shrubs take hold more quickly and thrive better.

Magnolias should be planted in the spring. They are often difficult to establish, but when well started are among the best of flowering trees. It often happens that only small plants are obtainable, especially of the rare forms. It is well to grow these on in pots for a year until they are well rooted, and then transfer them to the places assigned to them. The soil should be good to a depth that will make future transplanting unnecessary, for Magnolias are the most impatient of root-disturbance of all our trees. Hot drying winds in exposed places make sad work with newly moved trees.

Young trees or conifers planted in rows to grow on for later use should be moved at least once in two years to insure a good number of young fibrous roots in a compact mass. Young stock grown in this way is worth twice as much as

stock that has not been transplanted, and if the room can be spared to shift them, the labor is not too great when the results are considered. We find that this biennial moving does not in the least interfere with the season's growth of evergreens. The check given to the growth of deciduous trees and shrubs benefits them by making well-balanced heads, with fewer strong shoots that have to be pruned out later on. Those who wish to add to their collections new and interesting novelties as they appear, realize the value of this reserve nursery, and know, also, that newly purchased or rare trees are often too small to plant at once in permanent positions. If these are allowed a year or two in a temporary place, so as to become acclimated and of larger size, an opportunity is meanwhile afforded to select the best place for their permanent planting, and the planting of a tree needs careful consideration with a view to its maturity.

A reserve border of herbaceous plants is also desirable, made up of kinds recently raised from seed, and which will not flower for a year or more; of duplicates, others that are on trial as to hardiness or desirability, and new and unknown sorts, as a lot recently raised here from seeds received from Asia Minor. These unfamiliar plants should be kept where they are not likely to be rooted out by those unfamiliar with their appearance when the borders are weeded. We have to mourn the loss of many plants in this way, but a straight row in the reserve border is comparatively free from this danger. Such a border is useful, too, to fill up losses.

Narcissi are coming on better this year than usual, and we shall soon be able to cut the first flowers from the borders. Hardy Narcissi are more useful than is generally supposed. They provide the first outdoor cut flowers; they have a strength and beauty all their own, and last much longer than those forced indoors, for the sorts that are best as hardy plants are too valuable to be grown for forcing. They have also more substance, with distinct contrasts in coloring. They are for the most part of garden origin, the result of the hybridist's skill, and not mere wild forms, although the wild forms have much to recommend them. The substance of Horsfieldii, Empress, Emperor, M. Foster, Henry Irving and Golden Spur constitutes the value these species have when cut for use indoors. The continued cold of the past winter seems to have suited the Narcissi well. There has been no early start, with succeeding chills, such as occurred a year ago, and the tops have none of the seared look that they took on then. A good display of flowers is promised soon, and a healthy growth of the bulbs afterward.

The newly introduced Spanish forms of Narcissi have disappeared almost to a bulb; they proved unsuited to our climate, while, as already stated, the garden hybrids have the best constitutions and multiply most quickly.

E. O. Orpet.

A Few Desirable Plants.

A REMARKABLY handsome specimen of the Crimson Rambler Rose is now in bloom in one of the greenhouses belonging to H. H. Hunnewell, Esq., Wellesley, Massachusetts. There can be no doubt that this Rose is a decided acquisition. It has been thoroughly tested during the long and severe winter just past, and it has come through in even better condition than the majority of hybrids. It appears to belong to the robust Japanese form of *Rosa multiflora*, and is harder than the Polyantha type. It is a Rose of exceptional value as a pot-plant, judging from the specimen grown here. It is trained in pyramidal form and is completely covered with handsome clusters of deep crimson flowers. Evidently the current season's bloom is produced on the previous year's growths, which now are rapidly stretching out and promise to attain five or six feet in length on an undeveloped specimen. Strong plants are said to form shoots from ten to twelve feet long. On a pot-plant these shoots will be far too rambling in character, and in order to keep the plants in convenient shape for handling, they will need a little training—say, into balloon, fan or pyramid form, according to the grower's fancy.

Another climbing Rose now competing for favor is the Dawson Rose (*R. multiflora*, var. *Japonica* × *General Jacqueminot*), raised by Mr. Jackson Dawson, of the Arnold Arboretum, Boston. The flowers are deep pink, almost red, borne in clusters, and a trifle larger than those of the Crimson Rambler, to which it will be a fitting companion.

A few days ago I saw a plant of *Muhlenbeckia complexa* used as a basket-plant in the conservatories belonging to F. Simpson, Esq., of Saxonville, Massachusetts. I observed many years ago a plant of *M. complexa* which grew along the house

of Mr. J. C. Niven, curator in the old Botanic Gardens at Hull, England. It was diffuse rather than climbing, and had to be tied up to prevent its getting into the driveway. It made a pleasing border, the long, black, slender, shining branches spreading in all directions. As a basket-plant it is unique. In the specimen seen in Mr. Simpson's conservatory the branches drooped gracefully, and on the maturer side of the stems were bunches of its peculiar glistening, wax-like flowers. In the centre of the flower is a black trigynous seed-capsule, characteristic of the Buckwheat family, to which it belongs. It is a native of New Zealand.

A little more than a year ago I made reference in GARDEN AND FOREST to a fine collection of some two hundred plants of the large-flowered Christmas Rose, *Helleborus niger maximus*, growing in a set of cold frames at Mr. Powers' place at South Framingham. These are now in full bloom and make a beautiful show. There can be no doubt that this is the most satisfactory way to grow these plants. When treated as perfectly hardy plants they are a failure, and even if they endure the winter they seldom bloom. As their natural blooming season is early winter, any flower-buds which move, as they will do during a spell of mild weather, will be sure to be killed. Very little protection has been given these plants of Mr. Powers. They have simply been kept from moving. The foliage is perfect and, being evergreen, it is essential that it should be preserved. Our plants, exposed on the rock garden, are cut down every year. Since no foliage holds over to sustain the plants when making their spring growth they simply go back more and more, making it only a question of a year or two when they will die out entirely.

Wellesley, Mass. *T. D. Hatfield.*

The Earliest Daffodils.

THE first Daffodils appeared during Easter week. Always welcome flowers these, yet with their appearance there comes the thought that the first flush of the resurrection of plant-life is passed, for these blossoms mark the beginning of a second season and the flowering of the more showy plants than those of the early year. Nature performs her operations on a grand scale, and sometimes rather noisily, but there are none of her changes more impressive than the annual awakening of plant-life. A rare sight is the awakening, when one considers how seldom it can be enjoyed during an ordinary lifetime. I think it has been said that if Nature would usher in the spring-time with a brass band or some such noise mankind would struggle with each other to behold the sight.

Narcissi do not flower in constant order in my garden; it is partly a matter of location as to when they open. *N. bicolor* and its variety, King Umberto, were the first this year, with Henry Irving second. There are others—*N. pallidus præcox*, *N. obvallaris* and *N. nanus*—in flower now. *N. nanus* is a pretty little dwarf variety with long trumpets, which should grow out of a carpet made by some low plant, or it might do well in grass. The minute *N. triandrus* has established itself in the grass on one of my borders, and has not lately failed to flower.

Elizabeth, N. J. *J. N. Gerard.*

Christmas Roses.

HELLEBORUS NIGER is the oldest and best known Christmas Rose, but several other species and many garden hybrids and varieties are now cultivated under this common name. *H. niger* and its nearest allies bloom in late November and December in favorable seasons, but if there is much dull and cold weather then, as there generally is, the flowering is deferred until spring. It is also true that, even after a fairly good autumnal and early winter bloom, many buds are left which will open in early spring; this is most likely to occur with old and well-established plants. Altogether it is quite fair, in the average New England season, to count the black Hellebores among our early spring-blooming plants. Several fine specimens of the type and its progeny are just now passing out of flower. They are not easy plants to establish—just why it is difficult to tell; it is probable that the trouble comes from our hot and dry summer weather. The plants are received from foreign nurseries in December. They should be planted in pots of moderate size and kept in a cool greenhouse during winter; here, if well grown, they will flower. The growth begins after flowering and continues into late spring and early summer; while growing they require plenty of water and a partially shaded position. After growth stops they should be plunged out-of-doors for the summer, still kept shaded during the middle of the day and well supplied with water. With

this treatment they make excellent plants for forcing, giving abundant flowers during November, December or January, in a cool greenhouse, pit or frame. This method of handling, too, seems to be the best to secure good plants for the open ground—that is, they arrive too late in the season for fall planting, but by growing them a year in pots good specimens are procured, which can be planted in September or early October. In this way a larger proportion are likely to live and continue in satisfactory condition. They should be given good soil, a partly shady place, and kept well watered in July and August; a rock-work, with a northern exposure, is by no means a bad position. Almost all the garden varieties are good, and give many shades in color, from pure white to dull purplish red; none of the reds are very bright. Propagation is effected by division and by seeds; both these methods present difficulties not easily overcome by the amateur; it is best to import plants or to procure newly imported plants from the dealers.

Jamaica Plain, Mass.

B. M. Watson.

Pot Bulbs for Early Spring.

EARLY TULIPS FOR FORCING.—It was once held that only the early Tulips were suitable for forcing, but with me the Bizarres and Byblcemens have proved well adapted to pot-culture. There can be no question that the later ones, with their long flower-stalks and large cup-like flowers, are much the most effective as pot-plants. A little weak manure-water applied once a week after the buds show induces even larger and finer flowers than are borne on garden-grown plants, while the characteristic feathering and flaking, that in the later Tulips reaches perfection, make them especially beautiful.

IXIAS.—These plants, together with their allied companions, Sparaxis and Babianas, are also admirable for late winter and early spring flowers. Desirable as they are for lengthening out the nearly spent season of bloom under glass, there is considerable complaint that they are too uncertain in flowering to be satisfactory. The foliage often turns sickly and yellow, and frequently the plants do not show a single bloom. I am inclined to think that haste in forcing is the cause of three-fourths of these failures. A judicious letting-alone during the first few months of their growth is wholesome for them. Under the benches or beneath a flower-shelf, where they have fairly good light, but not enough to stimulate rapid expansion, is a suitable place through early and midwinter. Then, as the season of their flowering draws near they need to be brought to the light and watered more freely than before. Under this treatment they always give fine flowers and plenty of them.

Pineville, Mo.

L.

DOUBLE ENGLISH PRIMROSES.—For several years we have grown in the cold frames a few sashes of these flowers for early use in spring, and have been much pleased with them. Bunched like Violets with their own foliage, they are among the most beautiful of early flowers, and would, doubtless, prove almost hardy in sheltered places, though as yet we have not tried them. There are a number of varieties of double Primrose, but these are not to be classed with the Polyanthus, the former having but one flower on a stem, and these double varieties cannot be raised from seed as can the single kinds, but are easily increased in autumn by division. There are many double kinds cultivated in English gardens, all of which would be appreciated here if better known. Hitherto we have only grown the double white, but there are as many as ten or twelve kinds altogether, most of them of very old garden origin, especially the old double Velvet Crimson, which was almost lost to cultivation until recently. The treatment that suits the common single varieties of Polyanthus in summer will also suit the double Primroses. They need a moist shady place in the hot months, division in September in good soil, and protection in winter. If put in a dry place in summer the plants are liable to be a prey to red spider.

South Lancaster, Mass.

E. O. Orpet.

CYRTOPODIUM PUNCTATUM.—This is one of the most useful of the Orchids now in bloom, and it is so easily managed that no one need hesitate to undertake its culture. Fibrous loam, well-rotted manure and rough sand suit it exactly. The flower-stalks are from two to two and a half feet high, with large panicles of yellow flowers spotted with brown. The flower-spikes and the new pseudo-bulbs begin growth simultaneously. In the fall, after the growths have become thoroughly ripe, the plants should be allowed to rest until they show signs of activity in the early spring. While making growth the plants are much benefited by frequent doses of weak liquid-manure.

The Olive and the Lemon in Southern California.

To the Editor of GARDEN AND FOREST:

Sir,—In California's rapid development of fruit-production during the past ten years, two articles of great and growing consumption have been, until recently, almost entirely neglected. These are the olive and the lemon. Their history aptly illustrates the steps by which experience teaches the horticulturist in a new country the way to a profitable market. It shows, also, that the mass of men who engage in fruit-growing in such a country as California are unenterprising imitators, and that the few who have the courage and the skill to venture into a new field frequently reap almost incredible rewards before their monopoly is disturbed by their slower and less original rivals.

For a long time Mr. G. W. Garcelon, of Riverside, made a small fortune every year from lemons, while other growers made nothing. His lemons were fine, even-sized, well-colored, juicy, salable fruit. Other growers produced only a coarse, half-cured, worthless article. Mr. Garcelon sold most of his annual crop in San Francisco, frequently receiving five dollars a box. As from five to ten boxes to the tree is by no means an extraordinary yield, and seventy trees to the acre is a moderate planting, it is clear that his profits were very large. He was supposed to possess some secret and potent process of curing. Individuals and the state tried for a long time, without avail, to buy this secret, offering large sums for it. Two or three years ago Mr. Garcelon voluntarily divulged it for the good of the country, and since then more Lemon-trees have been planted than in all the years before. The secret proved to be only a very careful process of selecting, picking and handling the fruit and curing it at an even temperature and very slowly. The lemons remain in the curing-room from six to ten months.

The history of the olive was similar. The Messrs. Kimball, at National City, near San Diego, and Mr. Elwood Cooper, at Santa Barbara, realized great profits from olives. They sold the oil at from one dollar to two dollars per quart bottle. The output of Mr. Cooper's orchard of one hundred acres was, in 1891, 34,000 bottles. Yet, notwithstanding these reassuring facts, the ratio of lemons to California's entire orchard acreage, in 1892, was only one in forty. That of olives was even less, being one in fifty. This ratio has been somewhat increased by the plantings since 1892. The ratio of oranges, on the other hand, was three in twenty, a proportion which has decreased since 1892.

The Lemon is a more tender tree than the Orange, and more susceptible to injury from frost. For this reason sheltered, sunny locations must be sought for it. About San Diego there are thousands of acres of mesa and valley lands which are practically frostless. Many acres of these have recently been planted to Lemons and Olives, and more would have been planted had there been an adequate water-supply assured. San Diego has progressed so far in this direction that it has announced for this month the first Lemon Fair in the history of the state. At this fair the results achieved by the growers of San Diego County will be shown, and the latest methods of curing the fruit will be illustrated. For this purpose, certain enterprising growers have visited the lemon-growing districts of the Mediterranean, and have studied the curing methods in vogue there, which will be compared with home methods. Next to San Diego County, the Ojai Valley and other districts in Ventura and Santa Barbara Counties, Pomona, in Los Angeles County, and portions of San Bernardino County have been the principal centers of the increase in olive and lemon growing. In the production of olives they have gone ahead of San Diego.

The Lemon is, in a sense, a perennial bearer. The flowers and the green and ripening fruit are all seen upon the tree at the same time. The same statement has frequently but falsely been made in reference to the Orange-tree. The principal blossoming of the Lemon-tree, however, is in May, and the fruit is ready for picking in November. It is now usually kept in curing-rooms until the warm weather of the following summer creates a market for it. In this respect, again, the Lemon differs from the Orange, for the latter tree requires nearly a year to mature its fruit. The principal varieties grown in California are the Lisbon, the Eureka and the Villa-franca, each of which has its advocates. The industry is yet in its infancy. Its present status is illustrated by the results from seventy trees owned by one of my friends, whose trees are seven years old. They bore last year a crop averaging five boxes to the tree, and the crop was sold at \$1.15 per box,

on the tree. This fruit was purchased by dealers from San Diego, who shipped it to that city to be cured there for shipment east. For the year ending with June, 1894, lemons to the value of \$4,285,000 were imported into the United States. As compared with this total, the California product was an infinitesimal quantity.

A great many varieties of Olives have been tried in California, but the Mission, brought to the country by the Catholic Padres more than a century ago, still holds the lead. It is much smaller than the imported Queen olive, and it is permitted to become nearly ripe before it is picked. Its flavor is very different from that of the Queen, and at first is not usually relished as well. One soon acquires a taste for it, however, and in the local markets it is rapidly driving out the imported article. These olives have brought, at wholesale, this season, from sixty to eighty cents a gallon. It is very difficult to estimate the average product, but sixty gallons to the tree is not unusual in mature orchards.

The production of oil from the olive, whether on a large or small scale, is a very simple and inexpensive process. The essentials are a press of some sort, the more powerful the better, and great attention to cleanliness. The question of consumption of olive oil is largely influenced by the numerous adulterations upon the market, which are very extensively used. On account of their cheapness even druggists employ them in the preparation of prescriptions. Recent state legislation to prevent the sale of these imitations was easily evaded by the dealers who labeled their wares salad oil. The taste of the average consumer has been vitiated in this respect as in everything else, and many prefer a half peanut or cotton-seed oil to the pure olive. The hygienic value of the latter is very great, and its increased use in the kitchen in the place of fat compounds, would undoubtedly lessen the prevalence of dyspepsia. Besides, as an article of diet it is clean and refined. If these truths could be impressed upon the American people, there would be a market for all the olives and olive oil that California could possibly produce. As the case stands to-day, the question of profit from olives is disputed. "Plant olives for your grandchildren" is an Italian proverb frequently quoted in California. Yet, instances of an average production of fifty pounds from five-year-old trees, grown entirely without irrigation, have recently been reported. From such instances some growers argue that the Olive will grow upon any kind of soil and with but little care. Others claim that it needs good soil and plenty of water and attention, and that its slowness in coming into full production makes a heavy drain upon the purse, and doubtless the latter view is the safer, all things considered. Yet, when full grown, the Olive is a very beautiful, hardy, long-lived and productive tree, and an orchard of such trees would be no mean inheritance for anybody's grandchildren.

Redlands, Calif.

Wm. M. Tisdale.

Notes from West Virginia.

To the Editor of GARDEN AND FOREST:

Sir,—Nothing that blooms at this season of the year is more beautiful than the flowering fruit-trees. At Rose Brake these are freely planted for ornament; here, a group of Flowering Apples; there, Wild Cherries and the Japanese varieties; over yonder, a mass of Chinese and Japanese Cydonias, while close to the house are planted Apricots, Nectarines and Hard-shell Almonds.

But, perhaps, the most beautiful group is composed of Flowering Peaches. The variety that is employed has large double blossoms of a rich carmine color. These bloom late in April or early in May. The Apricots, Nectarines and Almonds, planted for ornament and to form a screen for some outbuildings, are especially valuable because of their early bloom. The Almonds are the first to flower, and then follow the Apricots, Nectarines and Plums.

The pleasure-grounds during late April and May are thus adorned with very many trees in bloom, and the effect of so many fine groups is very beautiful. We prefer, for the most part, to keep each class of plants by itself. Thus the different varieties of Lilacs are all together in one shrubbery, and our Magnolias have a choice place apart.

In the group of Flowering Plums we have *Prunus Pissardii*, *P. Simonii* and *P. spinosa*, and several other varieties. Of these the Chinese Double-flowering Plum is the last to bloom in company with the dwarf Flowering Almonds, which it slightly resembles.

Of all these charming trees, perhaps, our favorite is the Japanese Weeping Cherry. It is so graceful in habit of growth, picturesquely irregular at the same time, that it is symmetrical, but not tamely so. It is unique among trees, and I do not

wonder that it is the favorite weeping tree of Japan. Our single specimen is about fifteen feet in height, and is now covered with buds of a fine shade of deep carmine, which a day of warm sunshine will develop into delicate pink bloom.

In a wild portion of the grounds ledges of limestone rock adorn the sides and crown the summit of a little hill, and here many Red Cedars have sprung up of their own accord. These form a beautiful background for the large-flowering Dogwood, *Cornus florida*, and Red Bud, associated so generally in our woods against just such a dark screen of evergreen foliage, and surrounded, as here, by Columbine and lichen-covered rocks. This is our natural rockery, and here we think cultivated plants would be out of place. This is the spot for Ferns and our native wild flowers, such as Blood-root, Twin-leaf, Hepaticas, Anemones, Dicentras and Violets. These are all now in bloom. The only flower not found in our neighborhood, which has here a place, is the single white, fragrant, English Violet, and this is very charming, naturalized in the grass, where it grows and increases rapidly.

Following upon three early springs, this April of 1895 seems abnormally late, but is not really so. For a number of years I have noted the time of flowering of many plants at Rose Brake. To take, for instance, the Forsythias, I find in my notebook, that they began to open their golden bells in 1888 on the 17th of April; in 1889 they commenced to bloom on the 16th; in 1890 they bloomed on the 14th of April; in 1891 they were beginning to flower on the 15th; in 1892 I found their first flowers on the 8th; in 1893 on the 7th, and in 1894, that exceptional and treacherous spring, they were in full bloom by the 24th of March! This year a few buds opened on the 13th of April. At the date of this article, which is the 17th, they are not yet in full bloom.

Chimonanthus fragrans is the first shrub to flower in our garden. Only one bud on a bush about three feet high survived the terrible cold of the past winter. One solitary bloom opened early in March. This is with us the first fragrant flower of the opening year. Almost all the earliest flowers are scentless, such as *Jasminum nudiflorum*, the Forsythias and many bulbs. But Violets, Hyacinths and fragrant *Narcissus* follow quickly in their train. However, the earliest *Narcissus* that blooms here is scentless, and is a few days in advance of the fragrant varieties. I think it is *N. princeps*, and it blooms a little later than the first Crocuses and Snowdrops. *Chionodoxa luciliae* is now at its best, and so are many Hyacinths. Peaches are venturing a few blossoms in this neighborhood, but the nights are still cold, and we are not beyond the danger of heavy frost.

Rose Brake, W. Va.

Danske Dandridge.

Some Hyacinths and Grape Hyacinths.

To the Editor of GARDEN AND FOREST:

Sir,—It may help some of your readers to identify the plant described in GARDEN AND FOREST for April 10th as *Hyacinthus ciliatus* (*Muscari azureum*), if they are reminded that it is more commonly known in gardens as *Hyacinthus azureus*. It was first described by Baker as *Muscari lingulatum*, under which name it has been previously described in GARDEN AND FOREST. It has the habit of *Muscari*, with the campanulate flowers of the Hyacinth, and is evidently one of the hybrids common in the Lily family, and Baker, in the *Journal of the Linnaean Society*, vol. ii., page 427, named it *H. azureus*. It was figured with a colored plate in *The Garden*, August 10th, 1889. It has been collected in the Caramanian and Cilician Taurus, and is sometimes offered in trade-lists as *Muscari azureum* (Fenzl.). While its effect is that of a rich azure blue Grape Hyacinth, a slight examination will show that the individual flowers are dissimilar. It flowers here with the second early Snowdrops, and is valuable for its earliness as well as its rare color. It usually produces seeds, and with these and offsets a stock should be worked up to form a good colony, as it will require a few score of plants to secure a good effect in the border.

There is a beautiful blue *Muscari*, *M. Scovitzianum*, which will not flower for several weeks, which is rather prettier than *Hyacinthus ciliatus*. It has a larger flowering spike, and the flowers are light blue of the purest, daintiest shade. A collection of Grape Hyacinths should always include the white variety of *M. botryoides*, which now commences to expand its grape-like flowers. It is difficult to separate the purple *Muscari*. A variety from the Taurus, which has been established here a few years, is very vigorous usually, and is an intense purple, shading to a lighter color at the top of spike. It is generally a February bloomer, but this season has flowered late and is much smaller than usual.

Hyacinthus amethystinus scarcely flowers until June. Its small bell-like flowers are borne sparsely on graceful scapes about three inches long. They are of a light amethyst-blue. This is altogether a most charming plant. From Mr. Whittall a few years ago came a few stray bulbs of *H. lineatus*. This seems to be the smallest member of the family. It has two lanceolate leaves, two to three inches long, and a short scape with a raceme of small blue flowers. A dainty plant for a rockery, it would be easily lost in an ordinary garden. It flowers in June.

The Land Birds and Game Birds of New England, with descriptions of the birds, their nests and eggs, their habits and notes, with illustrations. By H. D. Minot. Second edition, edited by William Brewster. Houghton, Mifflin & Co. 1895. 8vo.

The new edition of Minot's *Land and Game Birds of New England* cannot fail to receive a warm welcome from all students of our birds. The original edition appeared in 1877. Considered as the work of a lad of seventeen, it may fairly be called a remarkable production. Although showing at times immaturity of judgment, its value as a record of original field observation was generally recognized at the time of its appearance, and the appreciation of its merits in this regard has, perhaps, increased with the lapse of time. The character of the work is in the main careful and accurate, and no small skill is frequently shown in conveying the delicate impressions received from out-of-door study. The truth of a passage like the following must be felt by every bird-lover accustomed to afternoon walks in winter:

From my acquaintance with the Tree Sparrows, I have almost involuntarily learned to associate them with a winter's afternoon drawing to its close, a clear sunset, with, perhaps, dark clouds above, and a rising north-west wind which sweeps across the fields to warn us of to-morrow's cold. The almost mournful chirp of these birds, as they fly to their nightly rest, has always seemed to me a fitting accompaniment for such a scene.

A second edition was always contemplated by the author, and after his untimely death the preparation of it was intrusted to our most accomplished field ornithologist, Mr. William Brewster, who has brought to his task the good taste and ripe judgment that have made his editorial work a model of its kind. The original form of the text has been carefully preserved, and embodied in the notes the reader is put in possession of much information as to the general distribution of the birds treated of, together with such additional knowledge of their habits, notes, etc., as has been acquired since the time when the book was written. Such annotations must ensure for the work a fresh career of usefulness.

The book is handsomely printed. It is prefixed by an excellent portrait of the author, together with a simple but touching biographical notice by his father, and a judicious introduction by the editor.

Notes.

Among the plants in flower for Easter decoration in this city were a few examples of *Dicentra spectabilis*, and very graceful they were.

We have received from Mr. George Hanson, Jackson, California, some flowers of the beautiful yellow *Calochortus Benthami*, showing that on the foot-hills of the Sierras the flowering season is much in advance of ours, as here the leaves of these plants are just appearing.

During the months of May and June a series of lectures and field-meetings will be conducted at the Arnold Arboretum by Mr. J. G. Jack, for the purpose of giving popular instruction concerning the trees and shrubs which grow in New England. The instruction given is not technical, and a knowledge of descriptive botany is not essential for students. Their purpose is to indicate by comparison the easiest means of distinguishing common native trees and shrubs and of recognizing foreign species. The different species and groups will be studied

as they come into flower, and the ornamental and useful properties, as well as their habits of growth and other peculiarities, will be considered. Any person who desires further information in regard to these lectures may address Mr. J. G. Jack, Jamaica Plain, Massachusetts.

Mr. Joseph Meehan writes from Germantown, under date of April 17th, that the conifers there have, as a rule, suffered very little by the hard winter, the exception being the Hemlock Spruce, which is terribly browned, *Cephalotaxus* and many of the Yews, which are scorched. Deodar Cedars lost a few leaves on their upper branches, but they are already budding out freely to the very tips of their shoots. The Cedar of Lebanon is also quite unhurt. In sunny places *Forsythia suspensa* was in full bloom, and so was *Magnolia stellata*. The early-flowering Bush Honeysuckles, *Cornus mas* and *Daphne Mezereum*, are everywhere in flower.

It is well known that the common evergreen Live Oak, of California, *Quercus agrifolia*, is preyed upon in the neighborhood of San Francisco Bay by caterpillars of the California Processionary Moth, *Clisiocampa californica*, which often devour the leaves once and sometimes twice during the summer and have given many of the trees an abnormal mushroom-like shape by stunting their growth. Professor E. W. Hilgard, of the University of California, calls our attention in a private letter to the fact that the caterpillars of another moth, *Phrygandia californica*, which also devour the leaves of *Quercus agrifolia*, are defoliating the plants of the European Oak planted at Berkeley, although they do not often attack the California White Oak, *Q. lobata*, which is botanically closely related to the European species. Curiously enough, horses and cattle never browse on the foliage of the California White Oak, although the branches of this tree, which are pendent and often sweep the ground, are very accessible to them, but they will stand on their hind feet to devour the young shoots of the European species.

Some interesting investigations have been made at the South Dakota Experiment Station on the distribution of weed-seeds by winter winds. For example, the contents of snow-drift on plowed land two feet square, three inches deep and ten rods from any standing weeds, were melted, and thirty-two weed-seeds belonging to nine species were found in it. Other tests confirm the fact that seeds are carried great distances upon the snow. Another test was made by pouring half-bushel piles of oats and millet upon the snow-crust when the wind was fifteen miles an hour. Both millet and oats passed a point twenty rods from where they had been placed in forty seconds. A twenty-five-mile wind was found to drift wheat-grains thirty rods in a minute. Of course, when winds on the plains keep blowing in one direction for days, seeds will travel many miles. The moral of these investigations seems to be that in the great western plains, at least, bare summer fallowing and matured weeds in waste ground may help to scatter seed during the winter over great areas, and they will be buried in the soil when the snow melts.

In the April issue of *The Botanical Magazine* a plate is devoted to *Magnolia parviflora*, one of the species introduced into this country nearly a quarter of a century ago by the late Thomas Hogg, and largely propagated at the Parsons' Nursery at Flushing, but apparently only recently known in Europe. It is said in the description which accompanies the plate to be a native of the alpine regions of the Japanese Island of Nippon, or, as the Japanese usually call it, Hondo, where it is said to grow on the Hakone Mountains, on Hego-San, and at the foot of the volcano of Wunyen, the two last being localities we do not find in the gazetteers or in Mr. Chamberlain's excellent *Guide Book of Japan*. The best Japanese botanists, however, who have in recent years carefully explored the forests of Hondo do not believe that this is a Japanese plant, but, like *M. conspicua*, *M. Watsoni* and many other plants which they only know in gardens, that it was introduced from China, which, at the time of the introduction of the Buddhist religion, sent to Japan most of the plants which they had been cultivating in their gardens for nearly a thousand years.

There is but a small amount of wood in a broom, but so many millions of these implements are used every year that the consumption of wood for broom-handles is a considerable item. *The Southern Lumberman* states that while it would have been almost impossible to sell a broom-handle made of heavy hardwood a few years ago, at present the reverse is true. The manufacturer prefers hardwood because it does not require so large a bolt, can be turned down smaller and yet retain sufficient strength, and can be ornamented more cheaply and artistically. Brooms with hardwood handles sell more

readily and do not deteriorate in appearance like the soft wood handles. Any kind of inexpensive hardwood, such as Beech, Birch, Maple or Ash, makes acceptable handles, while springy woods like the Elms are not salable, because one essential feature of a good broom is a straight handle. The manufacture of broom-handles can only be made profitable when the timber runs largely clear. In the eastern states the timber waste in making broom-handles exceeds fifty per cent., while in the south-west it is usually less than twenty-five per cent. There are four factories in Amsterdam, New York, one of which has a capacity of 1,200 finished brooms a day. They use hardwood handles from the south and west and get them for less than the bolts ready for the lathe can be furnished from native hardwood. The handles are turned green and dried afterward. The large end on which the brush is wired must be thoroughly dry or the broom will work loose. The drying of the upper part of the handle is of less consequence, except in the saving of freight.

Strawberries from Florida are scarce enough to make prices high, and the best fruit, which is coming from the vicinity of Lawtey, in that state, sold on Monday for sixty cents a quart. A few strawberries have already been received from as far north as Charleston. Mediterranean oranges are advancing in price, but much of this fruit is still coming at a loss. Altogether, 110,000 boxes of Sicily oranges and lemons were sold here during last week. Some California mandarins, small, but of good flavor and quality, bring twenty-five cents a dozen, and grape fruit from Jamaica costs ten to twenty-five cents apiece. Fully 50,000 bunches of bananas were disposed of last week at auction at high prices. Six cases of grapes from the Cape of Good Hope, via England, were sold here last Wednesday; while they arrived overripe and not in the best condition for want of proper packing, the experiment will again be made next season. Nectarines and grapes from South Africa reach England in perfect order, and peaches from the same remote place have been sold in this city in midwinter at \$3.00 each. Above 150,000 bushels of Australian and Tasmanian apples have been imported into England this year, the season continuing for six weeks from the first of March. The fruit is shipped in cases containing one bushel. The original cost of these apples is eighty-seven cents to a dollar a bushel, the freight for transportation covering 12,000 miles is \$1.00 more, and, with other expenses added the fruit stands at \$2.12 to \$2.25 a case when offered to wholesale buyers in the English market. With American apples, these are considered the best apples imported into England. The American export season for apples is almost ended, and above 1,440,000 barrels have left this country for Europe since last August.

Although the Japanese Anemone was introduced into European gardens fifty years ago, and the famous white sport from its variety, *Elegans*, known as Honoreine Jobert, was disseminated as long ago as 1863, there have been few variations from these old forms, owing to the fact that the plant, as we know it, rarely, if ever, produces fertile seed. Mr. Emile Lemoine, in an interesting letter to *The Garden*, once more invites attention to the fact that the variety Lady Ardilaun is a true seedling. This plant was raised by Mr. Campbell, gardener to Lady Ardilaun, who, nine or ten years ago, observed a head of seed on a plant of the white-flowered *A. Japonica*. This seed was sown, and of the three seedlings thus produced one was conspicuously better than the others, having pure white flowers of great size and substance, a taller growth than Honoreine Jobert, thicker stems and larger leathery leaves. A remarkable thing about this variety, which was called Lady Ardilaun, is that it produces seed which ripens readily in the open air. Mr. Lemoine sent out a seedling of this plant last year, which bore a semi-double flower at the same time that the American Anemone, Whirlwind, was sent out. He has other seedlings now under observation, and since this sudden change in the habit of the plant—that is, since it has become fertile and seed-bearing—we may, without doubt, look forward to a great many new varieties, single, double and semi-double. Mr. Lemoine describes a plant exhibited last autumn with stems as thick as a lead-pencil, perpendicular, and bearing numerous flowers which stand erect on firm foot-stalks. These flowers are formed of three or four rows of undulated and hooded petals, looking like little cups. Sometimes there are sixty of these petals in a single flower. The color of the flower is creamy white, passing into pure white, and it is three and three-quarter inches in diameter. Of course, where forms are constantly changing we may look for some improvements, although it would be difficult to imagine any flower which can excel in purity of color and grace of bearing the white-flowered Japanese Anemone as we know it.

The Metropolitan Parks of Boston.

LIKE the memorable preliminary report of 1893, the second annual report of the Metropolitan Park Commission of Boston forms a contribution to the literature of public open spaces of great general interest, as well as of more immediate local concern. The first regular report was issued so soon after the creation of the commission that it formed a document of but slight scope, although the remarks of the landscape architects, Messrs. Olmsted, Olmsted & Eliot, concerning some of the conditions governing the establishment of public reservations, and particularly the definition of their boundaries, were of universal application. The present report is a work which may well make the people of Boston realize what invaluable treasures they possess in the magnificent public reservations that have already been established, as well as quicken their appreciation of the possibilities for enlightened municipal development that are contained within their metropolitan territory.

The wealth of illustrative material enhances greatly the value of this report. Besides a panoramic view of the vast reach of landscape, looking easterly from the highest eminence in the Blue Hills reservation—still called by its commonplace modern designation of Great Blue Hill, instead of its ancient historic name, Massachusetts Mount, which by all means should be restored—there are a number of beautiful photogravure plates, representing various notable scenes in the various reservations, such as the falls, the brook and the noble Oaks in the Beaver Brook reservation; a pleasant woodland interior showing how some of the old “wood-roads” in the Middlesex Fells have been improved for temporary use; and scenes from the borders of various pieces of water in the reservations, including an exceptionally lovely prospect over the Stony Brook Woods, across to the Blue Hills range, with Turtle Pond nestling in the middle distance, amid a sylvan setting. Then there are excellent maps of the several reservations, a diagram showing the relations of the Blue Hills and the Fells Parkways to the metropolitan district, and a careful enumeration in an outline sketch of all the

landmarks visible in the panorama on every side from the Great Blue Hill.

The commissioners report takings to a total extent of 6,070 acres in the four reservations, which they have thus far laid out, while previous takings, amounting to about 1,600 acres, increase the total area in charge of the commission to nearly 7,700 acres. Altogether the total open space for recreative and water-supply uses in the Boston metropolitan district now amounts to almost 14,000 acres. The commissioners discuss their important trust in a conservative spirit that inspires confidence in their capacity for its proper administration. Great activities, yet scarcely entered upon, await them. These include the complicated problem of Charles River, the contemplated taking of the grand stretch of ocean shore at Revere Beach, and the providing of suitable facilities for access to the various reservations by means of parkways and boulevards.

The discussion by the landscape architects of various questions connected with the acquisition and development of public reservations, is of such general application and importance that it should be brought to the attention of park commissions, city authorities and students of municipal economy everywhere. Resuming the consideration of the boundary question, it is pointed out how it has not been the habit of park commissions, speaking generally, to give much attention to the boundaries of public reservations.

It is generally easier to acquire the whole of a given parcel of real estate, though half of it is not really wanted, and then to omit the purchase of any of the next parcel, though half of that is sadly needed, than it is to acquire a part from this and a part from that for the sake of obtaining what is essential and omitting what is of less importance to the landscape of the domain to be preserved. There are few public grounds which are not grossly deformed by the imperfections of their boundaries. Almost everywhere the immediate saving of time and trouble for the surveyor, the conveyancer and the commission concerned has worked permanent injury to public interests in public scenery.

It is pointed out that these large reservations have been taken not for the sake of making an exhibition of fine trees, economic forestry, model roads or any other special thing or things, however desirable, but simply in order to provide the metropolitan community with fine scenery; and consequently that all work done within the reservations ought to be directed solely to preserving, enhancing or making available the charm, the beauty, or the impressiveness of that scenery.

The scenery of all the reservations thus far acquired is essentially sylvan. Sylvan scenery is compounded of the shape of the ground and vegetation. The variously sculptured or modeled forms of the earth's surface furnish the solid body of landscape which man seldom finds time or strength to mar. Vegetation, on the other hand, supplies the dress of living green which man often changes, strips away or spoils, but which he can generally restore if he so chooses.

Emphasis is laid on the necessity of regarding the ancient wood-roads that have been opened up in the reservations to serve pressing administrative needs as merely temporary affairs. They do not and cannot be made to exhibit the scenery as it ought to be and may be exhibited. The report states that one may easily drive through the whole length of the Blue Hills range by the present service road and come away disappointed, and that, contrariwise, it is easily possible to imagine a road along the range which, presenting one quiet or surprising picture after another, could not fail to awaken admiration of scenery in every observer. The reservations will not return to the community that dividend of refreshment which is rightly expected of them until roads and paths shall have been built with special reference to the exhibition of the scenery. Prolonged study, not only of the ground, but of complete topographical maps, is shown to be essential to the devising of such roads.

The opening or closing of vistas, and the modification

of vegetation for the sake of scenery, is work that is greatly needed in the woodlands.

Excepting work directed to ponding or turning water, the selection of high or low, evergreen or deciduous, crowded or separated types of vegetation is practically the only work which can be done for the enhancement of the beauty of the landscape, and work of this kind, well handled, will be productive of remarkable and important results. In general, this work ought to be directed to the selection and encouragement of those forms of vegetation which are characteristic of each type of topography. Sameness of treatment, regardless of site and exposure, is to be scrupulously avoided. On the windy summits of the Blue Hills the dwarf growths native to such hill-tops ought to be preserved or induced to take possession. On sunny crags and ledges, Pitch Pine, Cedar and Juniper should be led to find place, while the Hemlock should appear among shady rocks. At the bases of bold ledges now concealed by dull curtains of stump-growth, large areas may profitably be cleared and even pastured for the sake of exhibiting the forms of the rocks and the grand distant prospects discernible between them. In other places, where only short-lived sprout-growth now exists, seedlings of long-lived trees should be encouraged to start. On slopes of poor soil permanent thickets may be advisable, while some rich glade or valley may be devoted to the development of soft turf and broad-spreading trees. There is thus no limit to the variety of sylvan types of scenery which may gradually be developed within these broad reservations.

It is stated that the more delicate and difficult operations of this art of enhancing the beauty of the vegetal element in landscape must wait upon the building, or at least the planning, of the permanent roads and paths. These roads, it is stated, must be made to exhibit the scenery, and the vegetal scenery must be improved with reference to the roads.

Careful studies of the present conditions of the reservations have been wisely determined upon. For example, groups of competent naturalists have volunteered their services in the study of the flora and the fauna of the several localities. Their notes and their collections will be carefully preserved for reference, and will present invaluable means for comparison as time goes on and changes gradually occur.

Notes upon Poisonous Plants.

FATAL cases of poisoning by eating roots of wild plants, brought to our notice in the pages of the daily prints, again remind us that much remains to be learned by grown people, as well as children, concerning the very active properties of many of our common plants.

It was probably not in the mind of Senator Hatch and others in establishing departments of research in each state that such should be in any direct sense life-saving stations. If these experiment stations are to make life richer in a fuller knowledge of methods of crop-growing they may well find it a part of their work to make human life safer by diffusing information concerning, for example, the poisonous plants that surround us on every hand.

On account of appeals that have been made to the New Jersey Station for facts concerning poisonous plants, and in the face of the many fatal cases of poisoning that have occurred about us, I have been led to look somewhat systematically into the subject, and as a result no less than sixty-five species of plants have been listed and placed upon the roll of suspects. Of these many are injurious only to a slight degree, and that effect is not constant. Some persons can work daily among the roots and fresh leafy shoots of the Poison Ivy, *Rhus Toxicodendron*, without injury, while on the other hand other persons cannot pass near the plants without experiencing physical discomfort. I shall not soon forget the time when both my eyes were swollen to blindness by handling this plant. Many of the plants upon the list are poisonous only when taken into the system. In other words, the poisonous plants may, for convenience, be divided into those poisonous to touch (by contact) and those which are poisonous when eaten (by assimilation). It is to the latter class that attention

should be most emphatically drawn, for these do the most injury.

Twice in the year there are outbreaks of poisoning. One of these occurs in spring, when every one is longing for some green thing, and most frequently the poison is taken into the system in the form of roots. Boys and others "go aforaging," and by accident or otherwise unearth some large fleshy roots; upon tasting them they are found to be sweet, or, at least, not disagreeable, and the mischief is begun, which ends in sickness, and sometimes death. The chances are that the fleshy roots belong to some species of plants of the Parsley family, some of the more common members of which are the Carrot, Parsnip and Celery, all three grown largely for food in the gardens. Even these well-bred plants are still somewhat poisonous to some persons. Thus there are cases of skin afflictions due to the handling of Celery-foliage, and some gardeners need to be protected against it if they work with these plants continuously. In like manner the Carrot is unsuited to some individuals as an article of diet, and when Parsnips are left to run wild in waste places for a few generations, a generation being two years in this plant, the root will become somewhat reduced in size and elaborate a poisonous principle that to many is positively harmless, and with others has caused death. This is by no means the only instance of culture holding the evil qualities in check. When cases of fatal root-poisoning occur it is not unlikely that they are due to the wild Parsnip, *Pastinaca sativa*. A more poisonous species of this Parsley family is the Poison Hemlock, *Conium maculatum*, which has come to us from Europe, and grows in waste places. This is a smooth, much-branched herb, three feet high, the stems of which are marked with purple specks, so that the name of Spotted Parsley is sometimes given to this species. The leaves consist of many leaflets and are ill-scented. A virulent poison, conicine, abounds in all parts, and should not be taken into the system.

A close relative of the *Conium* is the False Parsley, *Cicuta maculata*, also called Spotted Cowbane, Water Hemlock and Beaver Poison. This common species is a tall plant with the stems streaked with purple, but not spotted as in the *Conium*. The root is a deadly poison, and of all our poisonous plants is the part that causes the greatest number of deaths. Other species of the same family that are poisonous and have fleshy roots are the Water Parsnip, *Sium cicutaeifolium*, growing in wet places, and the Cow Parsnip, *Heracleum lanatum*, which is also a coarse plant fond of the low ground.

It is difficult to lay down any rule, hard and fast, to serve as an invariable guide and protection against these venomous plants. The danger of persons eating the herbage to excess is not great, but, as before stated, the injury usually comes from the fleshy roots, which are attractive to the eye and not disagreeable to the taste. These, if eaten in early spring, when they are gorged with the poisonous qualities, are quite sure to lead to unpleasant, if not fatal, results. Every one should be impressed with the fact that some of these poisonous plants pass the winter chiefly as large fleshy roots and are to be shunned. Nothing in the form of wild plants should be eaten unless well known to be harmless, and fleshy roots particularly should be avoided. Most particularly of all let parents and school teachers admonish children of the great danger of promiscuous foraging in fields and woodlands, especially in early spring.

The second outbreak of poisonous cases comes with the ingathering of toadstools during the summer. This subject was fully treated in GARDEN AND FOREST by Dr. Farlow, under "Notes for Mushroom Eaters," about a year ago.

There are a number of plants, particularly in the Heath family, Ericaceæ, that injure live stock, as, for example, the Calf-kill, *Leucothoë racemosa*, and Lamb-kill, *Kalmia angustifolia*, as the common names strongly indicate.

Four Native Trees in the North-west.

THE importance of proper selection of species for forest-planting was not realized by the early planters on the north-western plains, and to-day the picture of the decaying trees in these early groves is one of the greatest discouragements to forest-planting. The Cottonwood is pre-eminently a tree of bottom lands, and even here it is never crowded into compact groves, but rather spread out into an open belt of varying width, according to the character of the soil and water-supply. Since it is rarely found on the high prairies, one would hardly expect to make lasting groves in such situations, and yet this was the tree most extensively planted at first, and it has proved a failure everywhere except on the low plains. Its almost universal use may be attributed to the facts that it was considered a rapid-growing tree; that it was comparatively abundant and was easily propagated. But when we compare the growth of this species with that of some better native trees one is inclined to dispute the general belief that it grows much more rapidly than other trees.

In the college tree plats here on the high prairie, taking the growth for every year since 1889, the average annual growth of the Cottonwood has been 27.1 inches; that of the Box Elder has been 24.2; of the White Elm, 24.1, and of the Green Ash, 16 inches. It will be seen that the annual growth of the Cottonwood has been only three inches greater than that of the Box Elder and the White Elm, which last tree is counted among those of comparatively slow growth. Of the trees planted in the spring of 1889 the tallest Cottonwood is eighteen feet eight inches high and seventeen inches in circumference at the crown, while the largest White Elm planted in the same year was sixteen feet high and ten and a quarter inches in circumference. A Box Elder of the same age was fifteen feet high, and the best Green Ash was only ten feet and a half high.

This shows some superiority in the Cottonwood in regard to size, but when we examine the trees for hardiness or vigor one of the plats shows that of 330 Cottonwood-trees planted, only fifty-eight per cent. are living, while of 243 Box Elders, ninety-seven per cent. are living; of 111 White Elms, eighty-four per cent. are living, and of 121 Green Ash-trees, eighty-five per cent. are living. Forty-two per cent. loss in the case of the Cottonwood as compared with fifteen per cent. loss in the case of the White Elm is significant.

In addition, then, to the extensive failures of early plantings of Cottonwood, this comparison shows the fruitlessness of using this tree on high prairies. It shows also that although the Box Elder leads the White Elm in average annual growth and in hardiness of constitution—that is, in the percentage of trees that have survived the first six years after planting—it must be remembered that when full-grown the Box Elder is neither a shade-tree nor a timber-tree, while the Elm is both. The Elm grows more rapidly than the Ash, and, so far, it is less subject to insect pests, and, therefore, deserves a higher rank, especially where shade and protection is the object of the planter rather than valuable timber.

Foreign Correspondence.

Hippeastrums in England.

AT the present time the Hippeastrums are among the most showy and valuable of greenhouse decorative plants. Yesterday I had the pleasure of going through the houses devoted to the cultivation of these plants at the Chelsea establishment of Messrs. James Veitch & Sons, and was much struck with their wonderful variety and beauty. I gather from Bulletin No. 107 of the North Carolina Agricultural Experiment Station that Hippeastrums, or, as they are generally called in gardens, Amaryllis, are not grown to any great extent in the United States. This seems to me

a fact to be regretted, and I hope that some enterprising grower will take up the subject seriously. I have little doubt that success would follow a genuine effort to popularize so gorgeous a flower, and one, moreover, which can be well grown without too much trouble.

THE PARENTAGE OF GARDEN HIPPEASTRUMS.—The race of Hippeastrums, as it now exists in England, is a creation of quite modern date. Some of the wild species or forms which have contributed to make the Hippeastrums what they now are—I am speaking, of course, of the purely artificial products of the gardener's art—have been in cultivation in this country for upwards of a century. *H. equestre*, from tropical America, and *H. Reginæ*, from Mexico, West Indies, etc. (introduced in 1728), have been the principal factors in furnishing the rich, deep red and crimson tints of the earlier hybrids; their influence can even now be discerned in some of the latest seedlings. *H. aulicum*, from central Brazil—introduced in 1819—and *H. vittatum*, an Andean species introduced in 1769, have also played an important part. *H. Leopoldi*, collected in the Peruvian Andes by Pearce and sent by him to Messrs. Veitch in 1869, and *H. pardinum*, also first discovered in the same regions as the last named by Pearce and sent by him to the Chelsea nursery in 1867, have been largely used by Messrs. Veitch in the production of their later seedlings, *H. Leopoldi* much the more extensively of the two. *H. reticulatum*, introduced from south Brazil in 1877, a rather small-flowered species well marked by the crimson veinings and reticulations of the segments, has given rise to a set of beautiful autumn-flowering hybrids, to which sufficient attention has not yet been paid. *H. solandriiflorum*, a species introduced from Brazil in 1820, is remarkable for its long-tubed greenish-white flowers, closely resembling those of some of the Lilies of Japan, the Philippine Islands, etc.; this has given rise to some interesting hybrids, but it has played no part in the production of the regularly formed almost tubeless flowers, which at present so attract the attention of the horticultural public at the spring meetings of the Royal Horticultural Society in London. In fact, the Hippeastrum has become a florist's flower. The green bar in the centre of each segment, perhaps derived from *H. psittacinum*, has been eliminated, and even the base of the segments of many of the dark-colored seedlings is altogether clear of any trace of green. In the light-colored seedlings the green is evident enough. What in England would be regarded as a very great acquisition would be a race with white or blush flowers of as good form and substance as the beautiful rich red ones without the green eye which at present is so conspicuous. Five years ago Mr. Harry Veitch read a paper on the Hippeastrum at one of the meetings of the Royal Horticultural Society, and any one wishing to take up the cultivation of this beautiful genus should not fail to consult this paper, published in full in the society's journal. An extract of a few lines will show what has been done from a gardening standpoint: "Comparing the latest acquisitions with the original species in respect of size, we find that the flowers of the latter range from two and a half to five inches diameter, with segments from three-quarters to one and one-fourth inches broad, and with tubes three to four inches long; that of *H. solandriiflorum* seven to eight inches long. Our best recent types have a diameter of nine to eleven inches, with segments three and a half to four inches broad, and the tube almost obsolete. As regards color, scarlet and red prevail in some of the natural species, crimson-scarlet veins, streaks and reticulations in others, and all with a larger or smaller green centre. . . . We have now an uninterrupted range of colors, from deep maroon-crimson through crimson, crimson-scarlet, pure scarlet, orange-scarlet, carmine, rose and rose-pink, to almost pure white, with striped and reticulated forms of all these shades of color." The dimensions above given, I may say, are now understated.

CULTIVATION.—The plan adopted by Messrs. Veitch & Sons is as follows: Two-thirds good fibrous loam and one-third cow-manure are brought together about the end of

July, and turned over and well mixed about three months later, taking care at all times to prevent the heap from getting too wet. Just before potting, nearly a third in bulk of sharp sand is added. Potting begins in mid-January, and the bulbs flower eight or ten weeks later. After potting, the pots are plunged; spent tan (stored for a year) from the tan-yards is the material used both at Chelsea and at Kew. No bottom-heat is applied at first, and if the soil is damp when used no water is given. For three or four weeks the temperature of the house is kept at fifty-five degrees, Fahrenheit; then a little bottom-heat is given, and the temperature is raised to sixty degrees. When in flower the plants may be moved into a cool house, but very little water will be needed unless the leaves are well developed. More failures result from overwatering than from all other causes combined. After flowering, the pot and half the upper exposed part of the bulb should be plunged again in tan and kept shaded during bright sunshine. A good syringing daily is advisable during bright weather. Bottom-heat, too, is beneficial. Growth is rapid, and the roots run through and over the pots for some feet into the plunging material. As soon as the foliage has attained full size the bottom-heat can be done away with; no shading is necessary, and gradually all light and air possible is allowed, and finally the pots are lifted out of the tan and allowed to stand without water on the beds until the potting season again arrives, when the old soil is shaken away and the dead roots removed. In good strong bulbs there will always be a number of thick, fleshy, healthy, living roots at potting-time, even after a drying of some months.

SEEDLINGS.—At Kew we flower numbers of these in less than two years from sowing the seed. As soon as ripe, say, in May, we sow the seeds in pans in a warm house. When large enough to handle, the young plants are pricked off into beds not too far from the glass, and are kept growing continuously until October of the following year. They are then ripened off and potted in January or February. We sow seeds every year, only allowing those plants to seed which possess the color, form or some other quality desired. By starting with a few good parents a fine series of beautiful seedlings is soon procured. Messrs. Veitch never use manure-water at all, and repot every year. Others are equally successful by treatment widely different—that is, by never shaking out the bulbs at all, but repotting in slightly larger pots until the limit is reached, and using manure-water carefully during season of growth. A little crushed bone mixed with the soil is beneficial. The way we manage the bottom-heat at Kew is to have hot-water pipes—provided with valves, so as to regulate heat or stop it altogether—underneath the plunging-beds. The side walls which support the slabs on which the plunging material is placed prevent the heat from escaping laterally to any extent. By following such a course of treatment failure is practically impossible, but I am sure that in many parts of the United States really good results could be obtained by growing in cold frames. It is distinctly desirable to keep up a succession of seedlings, as plants propagated only from offsets have not the vigor of seedlings. Given good varieties to begin with, and cross-fertilization practiced only with vigorous bright colored or well-formed flowers, and all the resulting seedlings are well worth growing.

Kew.

New or Little-known Plants.

Rose, Belle Siebrecht.

AN illustration of this Rose, which is being distributed this year for the first time by Messrs. Siebrecht & Wadley, of this city, will be found on page 175 of this issue. The plant has already proved valuable when grown under glass. Its habit of constant bloom and the color of its flowers, which is a solid deep shade of pink, quite novel in Roses of this class, make it very useful for commercial florists. It is

a vigorous grower and an abundant producer of good-sized flowers; the buds tapering and borne on long stout stems well furnished with vigorous leaves. Another strong point in its favor is the singular purity and richness of its color as seen under artificial light, and it really shows up more brilliantly under these conditions than any of the Roses now grown for commercial purposes. We are assured that the plants have proved perfectly hardy in the latitude of New York for several years, and if it has a constitution to endure our winters it will be a most welcome addition to our hardy garden Roses, since we have so few which flower the season through.

The plant is said to have originated with Messrs. Dickson & Sons, of Newtownards, Ireland, and, under the name of Mrs. W. J. Grant, it received the gold medal of the National Rose Society at the Chester show in 1892. It is said to be a cross between La France, which came from the seed of a Tea Rose, and Lady Mary Fitzwilliam, which is also a Hybrid Tea. This parentage will account for its ever-blooming qualities and its delightful fragrance.

Plant Notes.

LINDERA BENZOIN.—This hardy native Benzoin, Spice-wood or Spice-bush, sometimes called Fever-bush or Benjamin-bush, may be considered as familiar to comparatively few people, either as a garden-plant or in its native habitat in our woods, where it delights in moist rich soils or along the courses of streams and rivulets. Under good conditions it becomes a tall shrub six or eight to twelve or fifteen feet high, and it is among the earliest, although it is not the very earliest, of our indigenous species to blossom. In flower it always attracts attention by its short axillary, umbel-like clusters of small honey-yellow colored blossoms, which appear thickly along the naked branches long before there are any leaves visible. The Spice-bush is dioecious, bearing its staminate or pollen flowers and its pistillate or fruit-producing flowers on separate plants, and the usually more numerous blossoms and the yellow anthers of the male or staminate plants give them a generally brighter aspect. The oval, smooth, shining bright red fruit, which matures in the autumn, is more conspicuous than the flowers, and remains on the plant until after the leaves fall, if it is not previously eaten by birds, some kinds of which seem very fond of it. In planting the Spice-bush for the autumnal fruitage a majority of the plants selected should be pistillate, but a few staminate plants should be placed among them, so as to insure fertilization. If, on the other hand, it is desired to get the best effect from the not very conspicuous early spring flowers the staminate plants would prove somewhat the most attractive. In a natural condition in shady places the plants commonly have a thin and straggling appearance, but growing in good garden-soil or by judicious pruning they form neat compact bushes. Although in nature the Spice-bush is generally found in moist situations, its free growth in ordinary shrubbery plantations or in garden cultivation shows that unusual moisture is not essential to its vigorous development. The leaves change to a pretty soft yellow color before they fall. All parts of the Spice-bush are richly spicy, aromatic, but this quality is strongest in the bark and fruit. In some parts of the country the people use an infusion or decoction of the twigs or bark as a drink in fevers or as a vermifuge, and the dried and powdered fruits were sometimes used as a substitute for allspice during the Revolutionary War. The benzoin of commerce is derived from an entirely different East Indian plant, or plants, belonging to another family. The drug was early known as "Incense of Java," or by the Arab name, "Luban Jawi." By leaving off the two first letters of the first word it is said the name gradually became corrupted and changed until it got to Benjamin, the product being sometimes known as Gum Benjamin, and our Lindera getting its occasional name of Benjamin-bush from some similarity in odor to the product from the oriental tree.

PRUNUS DAVIDIANA.—This fine, early-flowering Peach, or Plum, is now in full bloom in the Arnold Arboretum. It is almost wonderful to see this handsome tree, twelve to fifteen feet high, with its large white flowers, borne in the great-

Plum, is a mass of white—not absolutely snow-white, however, for a slight tinge of color heightens the effect. This plant appears to be perfectly hardy, but early frosts sometimes destroy or diminish the bloom in this vicinity, which

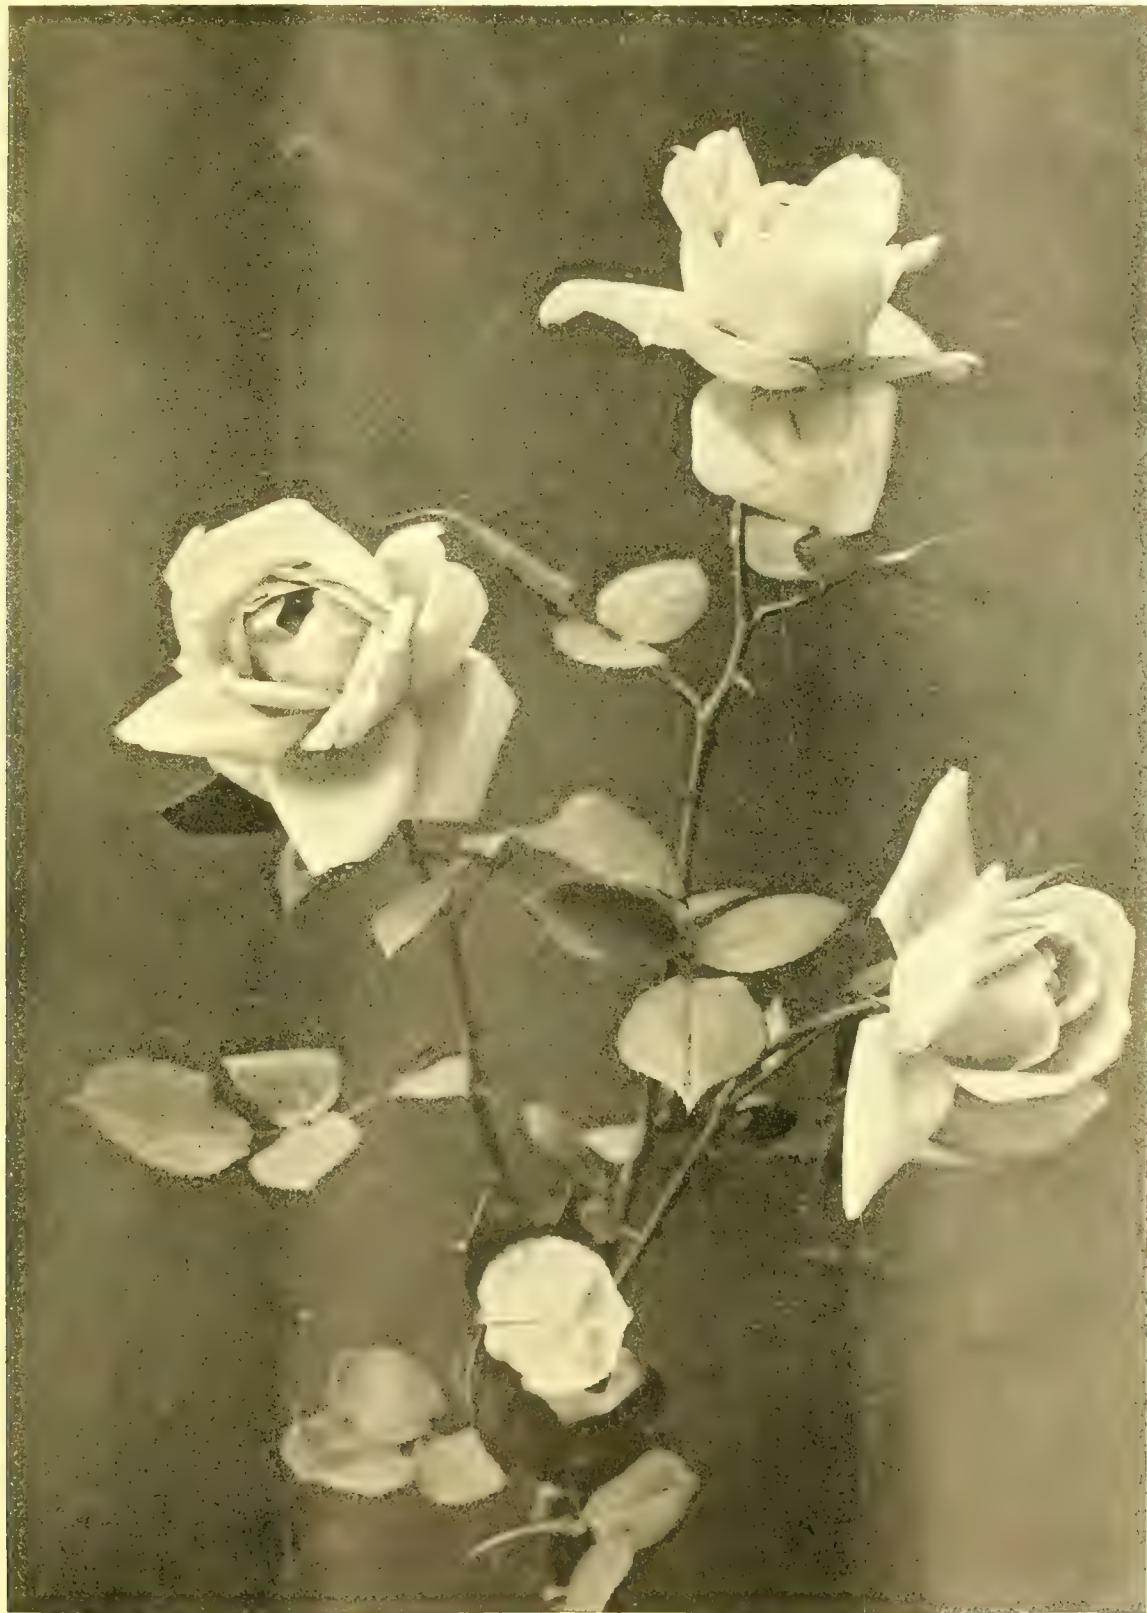

Fig. 27.—Rose, Belle Siebrecht.—See page 174.

est abundance, at this season before Forsythia or *Spiraea Thunbergii* even begins to show color. The flowers literally cover the tree; just as a little later, the familiar Peach, its close relation, is clothed with pink, so now, this Peach, or

is quite natural under the circumstances and not a sufficient reason for discarding it from our collections; one favorable season out of three would justify its cultivation. It demands the same sort of treatment given to the

Japanese Plums—that is, a well-drained soil, a sheltered position and plenty of food. The propagation is by grafting.

ERYTHRONIUMS.—Dog-tooth Violets are familiar wild flowers in the states east of the Mississippi, where carpets of their beautiful leaves are often seen in slightly shaded places. While the flowers are abundant in some cases, whole colonies of the plants will be found with few, if any, flowers during their season. This is owing to lack of maturity of the bulbs, and sometimes to their increase in numbers. The root-action and habit of increase of Erythroniums are curious and interesting and have given rise to much discussion. It occurred lately to one inquirer to investigate the real facts, which he discovered by cultivation in glass-sided boxes, and Mr. Blodgett, in the *Botanical Gazette*, vol. xix., page 61, has given a very lucid account of the reproduction of the species. The California Erythroniums are probably not much grown in eastern gardens, though they are perfectly hardy in this latitude and of the easiest culture. All the species are charming little plants. Their leaves are usually richly spotted and marked with colorations quite distinct from our eastern Adder's Tongue. *E. Howelli* has pretty flowers, salmon-pink in color. The leaves of this species are handsomely figured. *E. purpurascens* is deeper in its shadings, and is a combination of yellow and reddish purple. *E. citrina* has large flowers of citron-yellow, with a lighter centre. *E. grandiflora* and *E. Hendersonii* have respectively yellow and dark purple flowers. On strong bulbs the scapes will often bear two flowers. The effect of all these species is very pleasing and quite distinct from *E. Americanum*. They flower here in April.

TULIPA KAUFMANNIANA.—This beautiful Tulip is now in full flower, while the Duc von Thol Tulips, in the same border, are hardly showing buds, much less color; it is certainly the best early Tulip we have. It is a native of central Asia and has been in cultivation since 1877; it is apparently slow in propagation, or its merits are not widely known, for the bulbs are still difficult to obtain and are high-priced. The perianth is a bright sulphur-yellow, tinted with red, and as large as *Tulipa Gesneriana*; the peduncle is eight inches or more high, but varies somewhat, according to bad or favorable seasons; the leaves are large and glaucous. Taken altogether, it is a plant deserving high commendation.

IRIS ORCHIOIDES.—This Turkestan species is the second yellow Iris of the season, being preceded by the little *I. Danfordiae* by a month or more usually. *I. orchoides* is one of the Juno section, and Mr. Gerard, after testing it for three years, pronounces it reliably hardy here, and rather more robust than *I. Caucasicus*, *I. persica* and others of the same section. Heavy soil and a sunny location seem to suit it perfectly. It resembles *I. Caucasicus* in habit, though a taller plant, in having two rows of long tapering lax leaves clasping the stem in opposite rows. The stems are one and a half to two feet high. The flowers are small, but, as there are three or four opened at once usually on the same stem, a colony of this Iris is very attractive. Its leaves commence to appear very early in the season, and are sometimes touched by hard frosts. Curiously enough they were not injured at all this year, though the plants caught the early morning sun during the extremely cold early year, a most severe test for any plant. There is also a variety of this plant with lavender-colored flowers. *I. Caucasicus*, which flowers slightly earlier, might dispute the place of the second early yellow Iris, but its color is at best a greenish yellow, and the type is scarcely worth garden room.

IRIS SINDJARENSE.—from Mount Sindjar, Mesopotamia, has already been noted in GARDEN AND FOREST as a very handsome Juno Iris, with charming flowers of a light lavender hue and pleasantly fragrant. This has a habit similar to that of *I. orchoides*, though the stems are shorter, the flowers less frequent, and the leaves a darker green. The

flowers are also borne on shorter stems and are larger and more effective from their broader falls. This has survived two winters with Mr. Gerard, but does not seem as vigorous as *I. orchoides*. It commences to grow just before the end of November. *I. Sindjarense*, *I. orchoides* and *I. Rosenbachiana* are a trio of Irises of the same section which should please any grower of hardy plants.

NYMPHÆA FLAMMEA.—Flowers of this Water-lily have been sent us by Mr. J. Brydon, Yarmouthport, Massachusetts. This is one of a valuable series of hybrids produced by Monsieur Marliac, of which he gave an interesting account last year. It seems that he succeeded in securing a hybrid between a tropical *Nymphaea* and one of the hardy species of the north, and this hybrid produces seeds abundantly. Monsieur Marliac has in this way produced a series of hybrids, ranging in color from white to intense red. They generally bear medium or small-sized flowers; they are perfectly hardy and very free and continuous bloomers. *N. Laydekeri* of this series is now well known to growers of aquatics and is very satisfactory in cultivation. The flowers on first opening are a delicate pink, changing later to cherry-red. *N. flammea* appears to be of similar habit, size and character, but is much more intense in color. In the old flower sent us the color approaches that of *N. rubra*, but is not quite a self-color. Another variety, *N. ignea*, is said to be more intense in color. The new varieties, unlike *N. Laydekeri*, it is said, can be propagated by division.

OCHNA MULTIFLORA.—A London nurseryman recently reintroduced this stove evergreen, which was first brought to England in 1820, but somehow became lost for a long time. It is most attractive when in fruit. The flowers are somewhat like those of a yellow *Potentilla*. After the petals fade the calyx and receptacle gradually change from a greenish yellow to a rich vermillion; the receptacle enlarges considerably, and on it are the carpels, about six in number, containing the seed. The carpels, which are at first a pea green color, change when ripe to a deep purple, and give the plant a very odd appearance. It does well in a temperate house. The seeds germinate freely in a few weeks after being sown.

OXALIS BOWIEI.—To be in flower at this season these bulbs should be potted up and started in three-inch pots about the beginning of January. Afterward three or four of the plants may be massed in a wire basket and hung up in a warm greenhouse near the roof. Perhaps no other plant makes so pleasing a display of flowers and foliage for such a small sum of money. *Oxalis Bowiei* can be brought into flower at any time of the year by putting in the bulbs, in winter-time, about two months ahead of the time they are wanted in bloom, and in summer three or four weeks ahead of the time will suffice. It is unsatisfactory to buy mixed collections of *Oxalis*, since there are so many species of little or no value, and scarcely any two of them have the same habits. The flowers of *O. Bowiei* are a light rose color, and when well developed they are nearly two inches in diameter. *O. cuprea* and *O. versicolor* are two very good kinds; they have yellow and white flowers respectively.

Cultural Department.

Spring-flowering Bulbs.

MY custom is to uncover my bulb-beds during the first week of April. This is early enough for this latitude; indeed, some would consider it too early, but I do not leave the ground wholly bare. There will still be sharp frosts which will nip the tender shoots which have started beneath the covering, and so a little hay or other material should be left where it can be easily got when a chilly evening threatens. The young sprouts will become hardened in ten days so as to stand any cold which is likely to come. *Ixiolirions* will come up under covering so colorless as to appear almost transparent, and things as hardy as *Alliums*, when first exposed to the air, are unable to endure any frost at all. Then, why not delay two weeks longer? might be asked. For this reason: By the middle of April many of the early-starting things would be

grown so lank and long that they would be unable to recover their proper sturdiness. It is better to uncover too early than too late. Although the winter was severe, I find nearly everything has come through in good condition; indeed, much to my surprise, I find that some tubers of *Bletia hyacinthinæ*, planted four inches deep and entirely unprotected by covering, are alive and sound. Some tubers of *Smilax*, also uncovered, appear sound, but about them I am not sure. Both of these I have grown successfully out-of-doors with a few inches of leaves over them, and it now seems that even that precaution is not always necessary. Until three years ago I did not care much for *Ixias*—not that I did not admire their beauty, but it was too much trouble to grow them under glass; but of late I have grown them out-of-doors with complete success. They should be planted very late, so that they shall not make an autumnal growth (the end of November is a good time), and should then be covered with several inches of some material, the leaves of the Pine in preference. Over these I have heretofore laid shutters to turn off the rain, but I find this not really necessary; the bulbs will do as well without it, but will be a little later in starting. I planted last November a great many *Tritonias* and *Sparaxis* with the *Ixias*; the former are not yet up, but the *Sparaxis* are doing finely. *S. (Dierama) pulcherrima* is dead, I am sorry to say, and somewhat surprised as well, for Mr. Putnam has wintered it in Salem, twenty miles farther north than Canton.

The Snowdrops, of course, are past, but *Erythronium albidum*, which began to blossom before they did, has still a flower or two. The first *Narcissus* this year is *Minimus*, a perfect gem, of the same shape as *Emperor*, and comparing with it as David with Goliath. *Scoticus*, which usually takes precedence, is, as yet, hardly showing bud. The flowers of all varieties of *Narcissi* in my grounds are likely to be very few. No *Tulips* are yet showing color, the most advanced at the present time being *White Pottebakker* and *Tulipa Greigi*, the latter being bulbs kept over winter in the cellar, and planted out April 1st. I tried the same plan last year both with that *Tulip* and *Iris Susiana*, and found it perfectly successful.

Canton, Mass.

W. E. Endicott.

Work of the Season.

SPECIMEN *Gloxinias* are now in eight-inch pots, and the earliest have a good spread of leaves and promise to be in bloom by the middle of May. A second batch, from seeds sown late last summer, will come in July. They will be our earliest next season. We find it better to raise a lot of small bulbs each summer, as these always make much finer plants than seedlings raised the current season, no matter how early the seeds are sown, and, besides, it is easier to raise them during the heat of summer. Of late years we have found it better to keep the bulbs in the pots or boxes in which they have grown, than to shake them out and store them in sand. Whenever the bulbs shrivel, as they must when kept in this way, a loss of vitality results, no matter if they plump up when watered. Our bulbs are kept under the greenhouse benches, protected from the direct influence of hot-water pipes by boards. They will need water two or three times during the dormant season, but we always try them, and if firm they are passed by. Despite the moderate temperature, growth commences early in March, and as fast as a few leaves show we bring them to the light. Our finest plants last season were those which we did not repot. We grew them over, with the aid of a little manure-water, when coming into flower. Success with these does not depend so much on soil, although I used to think it did. Proper location is more important. The best structure to grow *Gloxinias* in is a low, close house, so ventilated that direct air does not strike them near the glass, but yet screened by a light shading. These conditions are essential. For a while our plants are kept on the dry side. In fact, they are never thoroughly watered until considerable growth has been made. *Gloxinias* are to a great extent surface-rooters, and to wet the whole mass of earth means stagnation. Proper aeration of the soil is important. Whenever we find a plant not doing well in a pot we can nearly always trace it to a defect in this particular.

Seed of Chinese *Primulas* should be sown now for autumn and winter blooming. I make no choice of the many strains offered. If obtained from a reputable seedsman they should be good. Free drainage and light soil are essential for these in the earlier stages. When well-rooted and ready to go into the flowering-pots late in August a little heavier soil may be used. Opinions vary on this point, and I have seen first-class *Primulas* grown all through the season in very light soil. The plants will do better during the summer months in cold frames having an easterly exposure, with the sashes slightly shaded

and well tilted to allow of free circulation of air, night and day. As naturally the plants bloom early, only large specimens can be had by taking out the flowering scapes as they appear until within three or four weeks of the time they are required to bloom. At the same time any poor varieties can be weeded out.

It is probable that many of the large specimen plants of *Cyclamen Persicum* exhibited in Horticultural Hall, Boston, at the last spring show, were two-year-old bulbs. It is a common practice to raise seedlings the preceding summer, and keep them growing for fifteen or eighteen months. For ordinary decorative purposes plants in six-inch pots, with about twenty-five flowers, are large enough, and usually can be grown from seeds sown in December. In the early stages light soil should be used. Some growers use dry sphagnum-moss, chopped fine, and broken charcoal mixed with the loam. Charcoal, as an auxiliary in draining and sweetening the soil, is not as generally used as it should be. Heavier soil may be used later. The summer treatment accorded Chinese *Primulas* suits *Cyclamens* exactly. *Cyclamens* have not done well with me of late years. I have been compelled to throw away handsome-looking plants every year, through attacks of the root-gall, presumably, nematodes of some kind. It is difficult to get loam free from them.

Looking months ahead, sometimes a whole season, we divide up our last year's stock of *Astilbe Japonica* for lifting next autumn. Those forced this season need resting; so also with *Deutzia gracilis*. A few cuttings put in every year keeps our stock replenished; soft shoots taken now from plants in bloom answer well. I can bear out Mr. Craig's statement that it is better to grow these plants altogether in pots, as I have grown mine in this way now for three years. It is better to propagate *Marguerite Daisies* and *Stevias* in June and grow them in pots than to plant them out. Thus treated they are more easily handled and kept in better shape than when planted out. The little blue *Paris Daisy*, *Agathæa celestis*, is an excellent winter bloomer. It is equally good in summer. It seems to me it would make a good bedding-plant, although I have never seen it tried. *Cytisus* of all kinds when small should be grown in pots; large specimens, with a good ball of earth, do better turned out. Indian *Azaleas* may safely be planted out, and even *Camellias*, but care must be taken that the surrounding soil is packed firmly to the ball of earth.

Wellesley, Mass.

H.

Indian Azaleas.

MANY people who have bought Indian *Azaleas* for Easter decorations will hardly know what to do with their plants when out of bloom. The majority, no doubt, were imported plants, potted in indifferent soil, as a medium for forcing and convenience in handling, rather than for growing them on continuously in the pot. All dead flowers, with the seed-vessels, should be picked off, and any soft growth, which often comes with the blooms, should be cut away, so as to keep the plant in neat bush shape. Ample time will be left for new and more even growth to develop and properly ripen before the autumn. It is customary in small towns to "board" the plants until the next season with the neighboring florist. This is, no doubt, a good plan for those who have no garden; but those who have—and such people are, as a rule, interested in caring for their plants themselves—will have no difficulty in growing them. They will do well in any good garden-soil. A partly shaded position is best suited for them, such as might be given on the north side of an Apple-tree or Pear-tree. In turning the plants out of the pots it will be found that very few new roots, if any, have been made. The original ball of earth should be pricked, or, rather, scratched, over with a pointed stick, so that the new soil will better adhere to it. The planting ought to be made in a slight depression or basin, with the ball covered not more than an inch, and the soil packed firmly about it, so that when water is given it should run through it rather than between the sides and the new earth. This is important. The planting out may be done any time after danger of frost is past, and from then until the first of September abundance of water should be given—twice a day during dry weather, and even a day or two after rain, although the soil may appear moist enough, it would be safer to give water. After the first of September less water will be needed, but it should never be withheld long enough for the ball to get dry. Some time in October the plants will need repotting, and as only a few fine roots will be found on the outside of the original ball a pot but little larger than the one in which it was flowered will be large enough. Some fine sandy loam should be carefully sifted in, so as to make sure there are no air-spaces left, and the whole made still further firm with a lath jammed in along the sides of the pot. The flower-buds will be already set, and

may be felt in the leafy tips of the shoots. The object now should be to keep the plants as dormant as possible. Very little light will suffice, providing that the temperature of the storage-place is low enough, say, forty degrees, Fahrenheit, not to excite them into growth. They may be kept in first-rate condition in an ordinary barn-cellars; even a house-cellars would do if shut off from furnace-heat. Water might be needed once a week or once a month; it depends on whether the place they are kept in is dry or moist. A month before Easter is early enough to bring them out into warmth and light, and they will bloom well in an ordinary house-window.

T. D. Hatfield.

Wellesley, Mass.

Notes on Carnations.

THE time for planting young stock out-of-doors is now close at hand and the plants should be gradually hardened off. Ours are now in cold frames, where they are freely ventilated, and some air is left on overnight, except when frost is threatened. In this latitude we usually commence to plant out from the 15th to the 20th of May. In some years there is a light frost after these dates, and Coleus or other tender bedding-plants are killed, but Carnations have not been damaged. We allow our plants eighteen inches between the rows and place them a foot apart in the rows. Between every fourth row we leave a path two feet wide. The plants can be topped and hoed from these paths and all weeds raked into them.

The soil best suited to most varieties of Carnations appears to be a rather light, sandy loam well enriched with manure. Certain varieties prefer a heavier soil, and the finest Grace Wilders I have seen were grown in a heavy clayey loam. As a general rule, however, we find that Carnations do best in a sandy compost. They also lift with much better roots at planting time.

Summer-blooming Carnation plants should now be nicely rooted in three-inch pots. These should not be stopped after this time if good flowers are desired by the middle of July. Mrs. Fisher is still the best all-around variety in this class. It is as satisfactory for summer flowers as it is unsatisfactory for winter blooms. Nobscot is unexcelled as a scarlet. William Scott and Daybreak are good bloomers of their respective shades of pink, and F. Mangold does fairly well as a crimson. We usually test a few plants of the newer varieties each season to try their capabilities as outdoor bloomers; it is possible some kinds, while not successes indoors, may prove useful outside. Young stock to be grown along for next winter's crop should be gone over at least once a week and stopped before running up too much. As a rule these are grown in boxes; if in pots they will need very careful attention in watering, as at this season they dry out rapidly. If they are becoming pot bound they should be transferred to a pot a size larger.

Carnation-houses will now need an abundance of ventilation. In addition to opening the roof-ventilator, some side or bottom air should be admitted daily on bright days unless a cold wind prevails. A good crack of air should be left on all night. Under no circumstances should ventilators be closed tight after this season of the year. On the morning of every clear day we give our plants a thorough good syringing; this is necessary to keep down that insidious foe, red spider, which will quickly ruin a batch of plants if these precautionary measures are not used.

Plants indoors are now giving an abundance of flowers. The individual flowers are diminishing somewhat in size, and as the beds are a mass of roots, abundant watering is needed and slightly stronger stimulants. We have gone over our plants recently, cleaned and tied them up for the last time, and after slightly loosening the surface gave them a mulching of well-rotted cow manure screened through a one-inch sieve. The plants repay this attention. Quite a number of growers do not stake their plants at all, and seldom or never clean them, at this season of the year. Plants so neglected show a marked contrast to those more carefully looked after. Certainly no one who has once staked and cleaned his plants will want to go back to the old careless and slovenly method of growing them. We find that during bright weather such as we are now having, our plants require a good watering every other day, and once a week we use stimulants. Some shade will now be needed on the glass. We use a mixture of naphtha and common whiting to which is added a little hard boiled linseed oil. The shade is applied with a common whitewash brush; it need not be put on thickly as yet.

Some Carnations which have not bloomed very freely during winter are now giving fine crops of flowers. Among pink ones

Ada Byron easily takes the lead with us. It is to be regretted that this variety is not a satisfactory winter bloomer. It has a beautifully fringed flower of good size and color, with a delightful odor, and is borne on a dense stout stem; we have not seen a burst calyx. As a spring and summer bloomer it is unsurpassed. Helen Keller, the best striped variety in commerce, is a grand sort grown as Messrs. Lonsdale and Daille-douze showed it at the Boston Carnation Show. We find, however, that it has a bad habit of "going sleepy" or fading out its blooms instead of opening them properly. Fully half the flowers on the small lot of plants we grew are useless, and other growers near by say theirs are similarly affected. We purpose trying ours in a heavier compost next season. Among pink varieties, William Scott is far the most consistent bloomer, and appears to give general satisfaction. Some growers still cling to the old Grace Wilder, and two thousand of these flowers which I saw recently were excellent, though in some instances the calyx was burst. Fred Creighton, another pink variety, almost discarded, was also noted in splendid condition. This variety gives a great spring crop of bloom, but flowers only moderately in winter.

Some of the new varieties sent out during the present year promise to be of first quality. Alaska, from Mr. Chitty, and Storm King, from Mr. Ward, are very highly spoken of by all who have seen them, and the Canadian variety, Bride of Erlestort, has many admirers. Meteor is bidding for popular favor as a crimson, while Mr. Dorner's Bridesmaid, Mr. Simmons' Rose Queen and Mr. Hunt's Peachblow are all promising pink varieties. It is unfortunate that the new yellow, Dean Hole, has been attacked by rust. There is much need of a good yellow, since none of the kinds at present grown are very satisfactory. A good scarlet which will bloom and grow as well as Portia, with flowers the size of Hector, is much needed. Hector is a fine scarlet, but it has defects in its lack of stem, bursting of calyx and fading out of flower. It is, however, a good Carnation, and the best one of its color now grown.

Taunton, Mass.

W. N. Craig.

Early Flowers.

THERE are few prettier sights in the garden on a bright sunny day of the early year than a bed of the little *Anemone blanda* or *A. Apennina*. I fear that there are few rarer sights than a good colony of the first species unless more care is taken of them than is usual in the average garden, for, like all plants which die down, in the early year they offer special opportunities to the destructive garden-helper. It will probably be found to be the best practice to take up the tubers when ripened and store them in sand in the early autumn, when they may be replanted. The small pieces of roots of this species usually received make large strong tubers, even in our heavy soil, and I think it is only the tidying up of the borders which prevents their constant increase, for a lot of tubers planted between Sedums and other plants, which are watered during the summer, hold their own. My impression is that *Anemone blanda* is adapting itself to our climatic conditions in its flowering period. Our winters are so variable that one can only arrive at an accurate conclusion after many years' experience, and this plant has been grown here only five seasons. When first grown it flowered about the first of January, the season being open. Since then the period of flowering has varied greatly, but on the whole with a later tendency. This year they are yet in flower at a time when *A. Apennina* is usually expected.

Up to the present time the garden is dependent almost entirely on bulbous plants for flowers, the few *Saxifrages* and small alpine plants not making much effect, and, in fact, being unreliable and uncertain here. As yet among the non-bulbous plants flowers are only found on Hepaticas, hybrid Primroses, *Dondia epipactis* and *Arabis alpina*, with the alpine Poppies and *Aubrietas* just opening. Hepaticas being abundant in the woods are too much neglected in gardens, where, in a suitable location, they thrive and are a capital illustration of the rare beauty of common things. I wish Primroses were as common as their beauty deserves. They are plants so easily grown and increase so rapidly that there seems no reason why they should not be seen in every garden, and at this season they cover themselves with lovely flowers, ranging in color from white, through the yellows and reds. A well-grown Primrose, with flowers on single stems, poised just over the lusty leaves, is a very pleasing sight. *Arabis* is the best white-flowered plant of the spring, as its prostrate growth is covered with sunny bloom. It has a pleasing way of wandering around the garden and showing at this time its flowers in new places.

Elizabeth, N. J.

J. N. Gerard.

Greenhouse Plants in Bloom.—Among the noteworthy plants in bloom here at the present time are several good old things which are not so well known as they might be. Among the climbers, *Petraea volubilis* is quite a pleasing sight. The flowers are arranged in long racemes opposite each other; they are bright purple, both calyx and corolla being nearly of the same color. There is a white variety not very commonly met with which is a pleasing companion to the purple one. The *Petraea*, from its habit of growth, requires a position where it can be planted out. It is a quick grower, reaching a height of about twelve feet before it makes much of a show.

Adenocalymna comosa, a beautiful yellow-flowered Bignoniaceous vine, is blooming for the second time this season. In the large Palm-house it may be seen twined in festoons from Palm to Palm, and occasionally a long shoot hanging down, beautifully laden with flowers. This is a good vine for a large greenhouse; it seems to do equally well in sun or shade. It is propagated by means of cuttings taken off before the young wood begins to push out. The cuttings will root either with or without a heel.

Botanic Garden, Washington.

G. W. Oliver.

Adonis vernalis.—This thoroughly good plant is now in bloom, the large yellow corolla, with its deeply cut leaf, reminding one of the earlier Winter Aconite, and makes a pleasing successor. It is a native of southern Europe and is one of the oldest garden-plants, although, strangely enough, it is found in comparatively few American gardens. It is perfectly hardy and thrives in almost any soil and situation; it is a good plant for the rock-work on the garden border. One caution should be observed by those who try to cultivate it, and that is to avoid transplanting it too often; it should be planted where it is to stay and left undisturbed for years. With this treatment a single plant soon becomes a clump, bearing numerous flowers and making a bright feature in the early spring garden. The propagation is by division, but plants are so inexpensive that it is much better to increase one's stock by purchase. The best time for planting is October or early November.

Jamaica Plain, Mass.

B. M. W.

Correspondence.

Notes from the South-west.

To the Editor of GARDEN AND FOREST:

Sir,—We have just passed through the most severe winter known here since the war. Gladioli and Montbretias by the hundreds, Cannas and Dahlias by the score, that I have left for fifteen years in the open ground over winter, are this spring but bits of rotted pulp. *Solanum jasminoides*, *Physianthus albens*, *Antigonon Leptopus*, *Ipomoea Mexicana* and *Manettia cordifolia*, all beautiful half-hardy vines that for a half-dozen years have stood the winters unprotected, sheltered only by a lee of the building, are dead as the proverbial nail this spring.

On the other hand, Peach-trees, the blossoms of which were killed both last year and the year before, were remarkably full of bloom this year, and I have never seen my Tea and Hybrid Perpetual Roses with so little dead or unsound wood on them at this season of the year. It is a matter of comment how full of bloom all shrubs and trees are. It is worthy of notice, also, that none of the hardier plants, Hyacinths, Tulips, Crocus, etc., were injured in the least.

The lesson is plain. We people of the south and south-west must protect half-hardy bulbs and tubers over winter by heavy mulching. To be sure, we may cover them ten times, and the ground never freeze below a two-inch crust; but the eleventh time an exceptional winter may come, and the ground freeze to more than twice that depth, when the entire stock gathered together through many a laborious year will be lost. If this mulching is of rotted manure the labor need not be lost in any event, for by spring it is more rotted and friable, and can then be dug in the beds to enrich them. Some of our beds were lightly covered with manure last fall. In these quite a number of half-hardy bulbs survived. A deeper covering would have saved them all.

One of our Pear-trees is showing a singular freak. It is covered with extra-large flowers, each distinctly semi-double. Each blossom has from ten to twelve broad, white petals, and the large clusters are very ornamental.

Pineville, Mo.

Lora S. La Mance.

The Hardiness of the Cherokee Rose.

To the Editor of GARDEN AND FOREST:

Sir,—On page 114 it is said that the Cherokee Rose is tender, and in the north suited only to the greenhouse.

Will you permit me, in the interest of the wider open-air culture of this handsome Rose species, to say that a plant of *Rosa Sinica*, obtained two years ago from Messrs. W. Paul & Son, of Waltham Cross, England, has not only survived the past winter here with absolutely no protection, but has now broken vigorously into leaf almost to the tips of its spray-like growth. Thirty-three degrees of frost were registered by the thermometer in the screen and continued high winds prevailed.

Salem, N.J.

G. L. C.

[The Cherokee Rose, as naturalized in this country, is not hardy as far north as New Jersey. It will survive mild winters in Washington, but is not reliably hardy there. It is a noteworthy fact, therefore, that a plant of this species has survived the late trying winter in Salem, New Jersey, and it would be very interesting to know from what quarter Messrs. Paul & Son received their stock. It is a well-known fact that plants of the same species vary in their ability to resist cold when taken from a more southern or more northern part of their natural habitat. Thus, the so-called Japanese Persimmon, or Kaki, is only known in this country as a semi-tropical tree, while plants of apparently the same species flourish in a climate as rigorous as that of New England, and, no doubt, seedlings from these trees would prove hardy in a much colder climate than the Kaki as it is known in Florida and southern California. It may well be that Messrs. Paul & Son have received some plants or seed of *Rosa Sinica* from a more northern region than that from which the original Cherokee Rose was derived. It is to be hoped that the stock from our correspondent's plant will be tried in still more northern latitudes.—ED.]

Recent Publications.

List of the Pteridophyta and Spermatophyta growing without cultivation in north-eastern North America, prepared by the committee of the Botanical Club of the American Association for the Advancement of Science, from the Memoirs of the Torrey Botanical Club. Volume V.

This book has grown out of the discussions of the principles of plant nomenclature which have been going on for the last ten years in the United States with much activity, and not always in the best taste. The matter was taken up by the botanists of the American Association for the Advancement of Science at their meeting held at Rochester, in 1892, where a committee was appointed which drafted the set of resolutions to govern the naming of plants, which have been adopted in the preparation of this report. It is unnecessary here to discuss the principles of this code, as they are now well known, and are substantially those adopted in this journal, and now by nearly all the working botanists of the United States, and it is enough to say, perhaps, that in most cases the catalogue appears to have been well done, although an examination of some groups will show that the compilers performed their work carelessly, or were not supplied with all the literature on the subject; and in other groups species have been proposed which can hardly be retained when the plants are studied by monographers from the point of view of their characters, and not merely of the names which botanists have applied to them, as must have been the case in the preparation of a catalogue of this kind in the short time that has been devoted to it. The names of plants are important, of course, to all working botanists, and it is well to have those of north-eastern North America arranged here conveniently with their synonyms; but, after all, the name of a plant is one of the least important things about it; certainly less important than its morphological characters, relationship, distribution, properties and uses.

It is now eight years since Professor Asa Gray died, leaving his *Synoptical Flora of North America* half-finished. The task of completing this great work, in which it was proposed to describe briefly all the plants in North America north of Mexico, fell upon Mr. Sereno Watson. He died three years ago, and since Professor Gray's death not a page of the *Synoptical Flora* has appeared. Now, however,

that the question of the names of the plants in one part of the country has been settled, or almost settled, perhaps the long-felt want of a comprehensive Flora of North America in compact form, and suitable for the use of students, may be supplied for them. Such a work can never be final, but it is absolutely needed, even if it is imperfect, to enable students and collectors in all parts of the country to carry on their investigations intelligently.

Notes.

Among the flowers for sale on the street-stands Marsh Marigolds, *Caltha palustris*, have been very abundant and popular during the week past.

The so-called Lemon-scented Verbena, from the western coast of South America, *Lippia citriodora*, is said to have been among the earliest of the shrubs planted in the southern part of California, where it is now one of the most popular plants, and attains the proportions of a fair-sized tree.

This is the autumn of the year in South Africa, and fresh grapes are now arriving in London from Cape Colony in good condition and are selling by the box at one shilling a pound. Boxes of Louise Bonne pears, each containing thirty fruits, have sold at thirty shillings, at which price some one ought to realize a handsome profit.

Would it not be more satisfactory if retail florists were more particular in giving customers the true names of plants and flowers which they admire? In one of the most aristocratic shops of this city a beautiful plant of *Andromeda speciosa* attracted much attention lately, and visitors who inquired what it was were calmly informed that it was a Canterbury Bell.

Mr. H. J. Hale writes to the *Florists' Exchange* that in his three-year-old Peach orchard, in Georgia, every one of the hundred thousand trees is loaded with fruit, and some of them now carry ten times too many peaches for a full crop. Much of this fruit will drop about the time when the pits are forming, but, allowing for this, the indications are that the trees will have to be hand-thinned and at least three times as many peaches picked from them as are allowed to remain.

A correspondent of *The Garden* writes that one of the great attractions at the recent bulb show in Haarlem were some groups of Tulip species. The very early and showy *Tulipa Kaufmanniana*, mentioned in another column of this issue, is said to have flowers resembling some of the Magnolia-flowers while in bud, but opening white, yellowish toward the centre, with a dash of red on the outside. *T. violacea* is also very early, and has bright magenta-red flowers. *T. linifolia*, named for its narrow leaves, has flowers of a bright scarlet. *T. Batalini* has a pure soft yellow flower, which is small, but very pretty. The early Irises also were said to have attracted great attention. The best of those which will flourish in this country have been more or less mentioned in these columns by Mr. Gerard.

The first California cherries of this year reached New York on April 24th, one week earlier than last year. These were Black Tartarians. Since then small lots of the white cherry Rockport Bigarreau have arrived, but the fruit is small and unripe. Ten-pound boxes are offered at wholesale for \$2.50. Some extra large Porto Rico pineapples are offered at fifty to seventy-five cents each. Easter Beurre pears of large size bring \$1.50 a dozen, and selected Newtown Pippins, from Ulster County, in this state, sell for \$1.50 a peck basket. Large bunches of Almeria grapes sell at the rate of fifty cents a pound, and Black Hamburg grapes, from Rhode Island, at \$3.00 to \$3.50 a pound. Strawberries, from Charleston, of fine color and flavor, said to be Hoffman's Seedlings, sell for sixty cents a quart.

Messrs. Ellwanger & Barry send us an extract from a letter which one of their customers has written to say that small plants of the Crimson Rambler Rose, in two and a half inch pots, set out in the open border last autumn, have stood the severe weather without any mulch, and are now beginning to make a good growth. This was in a climate where the thermometer fell to six degrees below zero during the winter, with much alternate freezing and thawing, and this speaks well for the hardiness of the Rose. On the other hand, we have a letter from Herr Max Leichtlin, who states that at Baden-Baden,

where the temperature once dropped to five degrees below zero, and at another time to eight degrees, the wood of the Crimson Rambler became brown, and the buds of these shoots are not starting as well as they should. The fact that strong shoots are coming up from the roots seems an additional proof that the exposed branches at the top had suffered very much. Herr Leichtlin adds that it ought to be said in favor of the Rose that last summer and autumn were extremely wet and cool, so that the wood did not ripen as well as it would naturally be expected to do in our hot and dry climate.

In the April number of *The Chautauquan*, Mr. Sidney Weyman has an interesting article on the German Forest, in which he points out that the value of the forest in its relation to climate and health is more fully appreciated in the German Empire and in Austria than in any other countries in the world. Its important place in the national economy is seen from the fact that the forests give employment to a quarter of a million of persons, and yet, more remarkable still, is the sentiment of affection and pride with which the people regard the forest as the dominant feature of the country. The forest has always played a great part in the history of the German people. In the early centuries the Germans were born and bred in the woods, and the forest still has a hold on the imagination of the people as a place of refuge and shelter and a home, a sentiment which we look for in vain among any of the Latin nations. The Frenchman retires for rest to the water-side, but the German seeks change of scene among picturesque forest sites, where the pure air is supposed to bring health and relief from all bodily ills. Week after week the nerve-racked German will spend whole days from morning till sunset in the woods. Many of the people have little taste for fashionable life and take their holidays in out-of-the-way nooks and corners, living in solitary forest inns and cottages for weeks together. Notwithstanding the enormous growth of the German towns the national love of the forest seems to have become more intensified. In the winter there are sleighing-parties in the woods, and at Easter and Whitsuntide the forests swarm with tourists, and the school youth of Germany make long pedestrian journeys through them in the spring. The rifle clubs and singing clubs of every town meet in the nearest wood, and to provide for these various festivities there are any number of excellent inns scattered throughout the length and breadth of the forests. Bismarck lives in the midst of an old Saxon forest, and the Germans love to erect the monuments of their great men amid forest solitudes. A great portion of the poetry and literature of the country is connected with the forest, and from Schubert's songs to Wagner's operas their music is saturated with forest sentiment, their dramas are set in forest scenery and deal primarily with forest life.

Kale, spinach and lettuce comprised the principal greens of the winter season, and these are still offered, with dandelion, tarragon, sorrel, beet-tops, mint and clumps of chives. Large quantities of radishes are coming from Norfolk, peas from Charleston and Savannah, and string-beans from Florida. Asparagus of excellent quality is being forwarded from points between South Carolina and New Jersey. The grade from Charleston known as Extra Fancy brings sixty cents a bunch, and choice asparagus from southern New Jersey costs fifty cents. New celery from New Orleans brings fifty cents for three stalks. Egg-plants from Florida are rare, and small ones command forty cents each. Crook-neck and green squashes cost ten to fifteen cents each. New potatoes from Florida are somewhat higher than those from Bermuda, and bring sixty cents a half-peck. Peppers from Cuba bring seventy-five cents a dozen, and okra, from the same place, ten cents a dozen. Hot-house beets from Boston cost twenty cents a bunch, those from Florida and Bermuda bringing nearly as much. Carrots, cauliflower and long English frame cucumbers also come from northern hot-houses. Mushrooms at eighty-five cents a pound, cranberries at twenty cents a quart and French artichokes at twenty-five cents apiece are among other staples on the best-stocked vegetable-stands. The superiority of vegetables carefully grown under glass over those which are grown out-of-doors in the south is seen in the fact that cucumbers from Louisiana and Florida are worth ten cents each, while those from Boston hot-houses command fifteen cents each. Tomatoes from Cuba, Florida and Bermuda are worth thirty-five cents a pound; those from northern hot-houses command twice that amount. What with modern skill in growing vegetables under glass, and increased means of transportation, it is now possible to find almost any vegetable in New York at any season of the year, with the exception of sweet corn.

Nature and American Literature.

EARLY in the year Messrs. Harper & Brothers published a book, by George William Curtis, entitled *Literary and Social Essays*. These essays, gathered by Mr. Curtis's literary executors from the various books and periodicals in which they were first published, extend over a period of nearly forty years. The sketches relate chiefly to the group of great Americans who were life-long friends of the distinguished author. Though Mr. Curtis was with us only yesterday, his recollections run back for half a century, and, therefore, in these reminiscences, we are brought face to face with the noble men who have given to American literature its chief distinction. And as under Mr. Curtis's sympathetic presentation Irving, Bryant, Thoreau, Emerson, Holmes and Longfellow pass in review before us, each in his habit as he lived, we cannot but feel that never did any group of men more thoroughly exhibit the true sanity of genius. The most pessimistic critic can find no trace of aberration in any of them, except in the unbroken spiritual solitariness of Hawthorne, or in the rigid adherence to a noble but somewhat impracticable ideal which set Thoreau forever apart from his fellow-men. Strong in moral purpose, self-reverent, self-controlled, these men have the rare distinction of having ennobled literature as much by their lives as by their works, and Mr. Curtis is of their kin. He had the same strong moral convictions, the same deep patriotism, and though he lacked the creative faculty, his critical gift was of a high order, and his literary style, even in his lighter work, has that unmistakable accent of high breeding which must be forever the despair of the mere dilettante in literature.

It rarely comes within the scope of GARDEN AND FOREST to take note of a book so purely literary in its quality as this. But Mr. Curtis, in his interpretation of the work of his great contemporaries, has so clearly, though perhaps unconsciously, revealed the ennobling influence upon thought and life, of a right love of nature, that we feel impelled to add a word of comment on this special topic. In all these men of New England birth, including Mr. Curtis himself, we note that, combined with their stern moral rectitude,

and having its root, perhaps, in the same source, was a deep and genuine love of nature, in which we trace the same earnest simplicity and sanity that marked their lives. And, as our attention is for the moment recalled to the work of these early interpreters of nature, we cannot but remark that they struck a deeper and fuller note than is sounded to-day by even the most sympathetic observers of the beauty of our fields and woods. Unlike some of our modern writers, who complacently accept the title of "High-priest of nature," these sincere men did not seek her solitudes primarily to make notes for a magazine article, or even for simple rest or recreation, but for spiritual strength and sustenance. Thus they always wrote with reverence of the beauty of the outward world, and in their work there is no trace of the petty egotism or of the restless craving for sensation which mars many of the so-called nature-records of this more flippant age.

This sensitiveness to the profounder influences of nature and to what may be called its spiritual beauty is most strongly marked in the men of Puritan descent, as if out of the strong had come forth sweetness, and it is conspicuous very early in the literature of the country. Mr. Curtis tells us that the school readers of half a century ago contained two poems which every boy and girl read and remembered. One of them was Bryant's "March," the other was Longfellow's "April," and though the curious reader may find in the first a more vigorous love of nature, and in the other a more tender tone of tranquil sentiment, both deal with the sights and sounds and suggestions of the American landscape in the early spring, and the chord, so lightly touched by the young poets, slowly swelled into rich harmony in the imaginative prose of Emerson, Thoreau and Hawthorne, the noblest of the group. In Thoreau this enthusiasm for nature was combined with a stern moral purity; in Hawthorne, with a rich, though sombre, imagination, and in Emerson, with a noble and serene philosophy, but in the moral fibre of all the three was the granite strength of the New England hills, and to their inspired imaginations the tranquil scenery about Concord was a symbol of the repose and balance and harmony of the universe.

In treating of Irving, Mr. Curtis brings us at once into a lighter, but still a wholesome, atmosphere. Irving, true son of the city that has always been cosmopolitan, cared for nature chiefly in its relation to humanity, and, though not indifferent to the grandeur and varied beauty of his native land, loved best the rippling landscape of England, made exquisite through cultivation, and in America the picturesque banks of the Hudson, which he has forever made his own by the right of the eminent domain of the imagination. The charming legend of Rip Van Winkle is, in Mr. Curtis's view, the more remarkable and interesting, in that, although the first American creation, it is not at all characteristic of American life, but, on the whole, is a quiet and delicate satire upon it. So, perhaps, it is to our credit that we love the kindly vagabond who asserts "the charm of loitering idleness in the sweet leisure of woods and fields against the characteristic American excitement of the overflowing crowd and the crushing competition of the city." Mr. Curtis, too, makes the acute observation that it is to the author of the *Sketch-book* and *Bracebridge Hall* that we owe the conception of rural England, whose charm yearly draws such hosts of American pilgrims to her shores. Only an American could have seen England as he described it, and invested it with an enchantment which the mass of Englishmen had neither suspected nor perceived.

Mr. Curtis's own attitude toward nature can best be noted in the essays which treat of Hawthorne and of Emerson. In these papers he has given us a description of Concord and its surrounding neighborhood, which is marked throughout by exquisite poetic feeling and the most delicate appreciation of its strangely tender beauty. Not only does he manifest deep insight into the profound significance of nature, of which its outward beauty is but the sign and symbol, but his ear is quick to catch the true note wherever

it is sounded, and in the very year that *Walden* was published he writes :

Thoreau's instinct is as sure toward the facts of nature as the Witch Hazel toward treasure. If every quiet country town in New England had a son who, with a lore like White of Selborne's and an eye like Buffon's, had watched and studied its landscape and history, and then published the result as Thoreau has done in a book as redolent of genuine and perceptive sympathy with nature as a Clover-field of honey, New England would seem as poetic and beautiful as Greece.

His interpretation of Emerson is, perhaps, even more sympathetic :

The imagination of the man who roams the solitary pastures of Concord, or floats dreaming down the river, will easily find its landscape in Emerson's pages. His writings have no imported air. If there be something oriental in his philosophy and tropical in his imagination, they have yet the strong flavor of his mother earth, the undervived sweetness of the open Concord sky and the spacious breadth of the Concord horizon.

Conifers in the West.

THE only conifer that can be readily grown in the west, in addition to the Pines already discussed in this series, is the Red Cedar, *Juniperus Virginiana*. It is found native along the Kansas, the Niobrara and other western rivers, and thrives in the dry ledges that border the streams. It is too slow a grower, however, to be an attractive species to the western planter unless he desires it to increase variety in his grove.

The European Larch was given a thorough trial at the South Dakota Agricultural College, where trees three to six inches high were grown for a year in nursery, and then set with Box Elders. During the first three years they made only a sprawling growth, the laterals being stronger than the leader; then they began their upright growth, and in the course of the next two years assumed their normal shape. But last spring they were almost completely ruined by a late frost. The Larch leaves out very early, so that when late frosts are apprehended it had best not be planted.

The Red Pine, *Pinus resinosa*, ought to be as desirable a tree for western planting, but it has not been given a fair trial, probably because it is not commonly offered by nurseriesmen.

The Arbor-vitae is not a success in the dry plains. A hedge of it was planted along the front line of the Agricultural College campus at Brookings, South Dakota, in 1887. It was heavily mulched, and grew well the first year, but, in spite of good care, it gradually failed, and now scarcely a vestige of it remains. Last October I saw a small hedge of it at Denver, Colorado, in fine condition, but it had been thoroughly irrigated.

It is difficult, if not impossible, to assign the Spruces to their proper places in western planting. The White Spruce, *Picea alba*, is a native of the Black Hills, and specimens of it pulled from the woods in that region and set in the forest-plots at Brookings are now making a slow, but healthy, growth. They were twelve to sixteen inches high when planted in 1889, and the tallest is now three feet eight inches high.

In several towns in central Kansas, such as Hutchinson and Salina, one sees Norway Spruces on the lawns, but they are not at all common. At the home of Secretary Morton, at Nebraska City, Nebraska, a Norway Spruce of his planting is now about thirty feet high, and measures thirty-four inches in circumference at three feet from the ground. Douglas Spruce, *Pseudotsuga taxifolia*, and the Colorado Blue Spruce, *Picea pungens*, have been extensively tested at Franklin, Nebraska. They are grown until twelve to eighteen inches high under shade, and are then transplanted into open nursery rows. The Douglas Spruce did not stand the extreme drought well, not a single good specimen being seen during my visit in October. This Spruce was also quite extensively planted in the Sand Hill experiment of the Forestry Division in 1889. In inspecting these

plots in October last, a very few Douglas Spruce were found, but none looked as if they could survive another year.

The Blue Spruce has a much better record. Many sturdy young trees of it can be seen at Franklin, and there are remarkably fine specimens to be seen in the cemetery at Nebraska City, and at Salina, Kansas, while it is the most common ornamental tree in the lawns of Denver, Colorado. It is a very slow grower in the plains. The trees at Nebraska City are not more than one-third as high as a White Pine on the same lot, and evidently planted at the same time. The Denver trees have the advantage of irrigation. This Spruce varies greatly in color, specimens having a heavy bloom on the foliage being counted particularly valuable for ornamental planting.

It may be that one of the Spruces named may succeed when planted in the shade of Pines, as the species are shade-enduring, and this probably accounts for their poor growth in the intense light and heat and drought of the plains.

A few specimens of Balsam Fir, and very rarely, toward the south, Silver Fir, complete the list of conifers seen in the west. For general planting the Pines must take the lead, and of these, *Pinus ponderosa* and the Scotch Pine are probably the most promising.

Washington, D. C.

Charles A. Keffer.

The Saguenay Region.—I.

THE gorge through which the Saguenay River flows is one of the natural wonders of the world. The deep stream winds but little, and its appearance is much like that of a narrow lake. The cliffs which wall it in are so steep and lofty that one who steams over its surface rarely catches even a glimpse of the country which stretches away from their tops. Ninety miles from the mouth of the river the gorge divides, the main part going on to Chicoutimi, the other extending a few miles south-west and forming Ha-ha Bay. At the head of the bay the rocky barrier is broken or worn away, and a wooded and grassy slope comes down from the higher land. Two rivers, the Ha-ha and the Mars, rush down the slope with many rapids and waterfalls, while smaller streams hurry into the bay through narrow gorges. At the mouth of the Ha-ha stands the village of St. Alexis, or Grande Baie, and by the mouth of the Mars, St. Alphonse, or Bagotville, the former names being most in use with the French Canadians. St. Alphonse is the principal landing-place for steamers, and is most picturesque in situation and surroundings, the rocks rising abruptly immediately behind the village. The heights above offer delightful views of the bay, and command a wide expanse which is bounded in the distance by low mountains, with an opening down the river. This village I selected as a place of rest and recreation in the month of August, making excursions into the surrounding region on foot, by boat, or by means of that universal vehicle of the rough country, the buckboard wagon. A shorter stop was made in the early part of September at Tadousac, near the mouth of the river, with a brief stay at Chicoutimi.

Aside from the scenery, in which the sublime and the beautiful are charmingly mingled, the region provides a varied field for botanical work. Along the sides of the bay the gneiss and granite rise in massive cliffs and ledges, or form low ridges which stretch away from the shores. Though frequently bare, many of them show characteristic rock vegetation, while others are more or less abundantly covered with Fir, Spruce and Pine. Back of these rocks, and overlying them as they extend away from the river, are clay lands, into which the streams have cut deep valleys, bordered with hills and bluffs along the watercourses. The clays are subject to extensive landslides, which considerably change the contour of the hills when of recent occurrence. They provide a good soil, and where they overlie the country is the principal farming region. Back of these and at a higher level are sandy lands, interspersed with Pine plains, with their characteristic plants. Only a few miles away are numerous small lakes, abounding in

trout and aquatic vegetation. There are many swampy areas, and springs are everywhere abundant.

The prevalence of Coniferous trees was to me the marked feature of the forests. What remains of the woods on the clay land is largely made up of deciduous trees, and this, to some extent, is true of gravelly and sandy land. But the Hemlock is commonly interspersed with them, with Tamarack, Fir, White Cedar and Spruces occupying boggy areas. The deciduous trees are chiefly the Canoe, the Yellow and the Cherry Birch, the White Elm, the two Poplars (*Populus tremuloides* and *P. grandidentata*), the Black Ash, the Red and the Sugar Maples. Among smaller trees are the Mountain Ashes, *Pyrus Americana* and *P. sambucifolia*, which, in rocky localities, are often reduced to shrubs, fruiting at the height of four or five feet. The Alders are among the most plentiful of shrubs, *Alnus viridis* growing in the rocky woods and on the ridges, while the Speckled Alder forms dense thickets by watercourses and in swamps, sharing the ground with various Willows, the Sweet Gale and different kinds of Cornel. The last are common in the soils of all land adapted to their growth, as well as species of Viburnum belonging to more northerly regions. The Staghorn Sumach and the Beaked Hazel-nut were frequently seen, bordering the woods or making clumps of bushes in the open fields. The Striped and the Mountain Maple bushes line the sides of ravines and hang over the streams, or are interspersed among the trees which cover the steep slopes.

The White and the Jack Pine were the only Pines noticed. They are mostly confined to the sandy or gravelly land, or are scattered about on the rocky ridges. *Pinus Banksiana* is abundant in the poorest soil, forming Pine Plains in the sand. In such localities it is usually a low bushy tree, becoming a mere shrub on the rocks, where it can root in the scanty soil of some crevice or cling to a narrow shelf. The Arbor-vitæ, growing in the thin soil of some of the ledges, also forms a shrub of straggling habit, spreading over the ground to a distance of two or three feet from the stem, and fruiting freely when but a foot or two high. In the areas of rock by the shores of the bay the Coniferous trees are often curiously intermingled. The water trickling from seams and crevices has given rise to growths of Sphagnum and other mosses, which furnish a soil in which the different kinds take root. Here the White Pine, the Larch, the Fir and the Spruce are in such close relations that their branches touch each other. Their differing shades of green are admirably shown by this proximity, and offer a picture that is always charming.

But little merchantable White Pine is left in the vicinity. It has all been appropriated by the lumbermen or destroyed by fire. The logs at the mill in St. Alexis, the only one which remains in use on the bay, were all from quite small trees, some barely eight inches in diameter. At Chicoutimi I found large mills supplied by the forests of the upper Saguenay and its branches, and which furnished its principal industry. Here many of the logs were larger, showing more available material, though much smaller on the average than those of the forests of the Great Lakes and the Alleghanies. The smaller logs were largely cut up into "deals" and "battens," planks four to six feet long and six to eight inches wide. They were principally for export to distant lands, many, I was told, going to Australia. Being quite free from knots, they make good material for all articles to which lumber of such small dimensions is adapted.

Chicago.

E. J. Hill.

What is a Cantaloup?

THERE is a dearth of distinctive terms at command for the classification of our rapidly multiplying varieties of garden vegetables. Every effort should be made to fix with clear definitions the few which we do have, and to discourage every tendency to their incorrect use. As new vegetables appear they too often receive incongruous or

unintelligible names, and the nomenclature of this class of plants has become almost intolerable.

One of the good words, now badly mistreated, is the term cantaloup, as applied to a group of muskmelons. As used at present the term is of doubtful signification. In the south it is applied generally to all muskmelons. Certain well-informed horticulturists of southern experiment stations have issued bulletins on cantaloups, and they include under this head all the varieties of muskmelons. According to a limited acquaintance with southern people, the term cantaloup, when applied more closely, means a muskmelon of the Nutmeg class, small, globular, netted and green-fleshed. In the north, cantaloup means just the opposite; that is, a large, ovoid, rather smoother, yellow-fleshed fruit. The varieties bearing the names Cantaloupe, Improved Cantaloupe, etc., sent out every year from northern seedsmen, are of the latter description.

Probably the term is incorrectly used in either case, though its application to the small, netted, green-fleshed melons, is doubtless farthest from propriety. Naudin, whose work I do not have at hand, is quoted by Bailey* as "the most excellent authority upon the cucurbits," and from him Bailey adopts the following definition of Cantaloup (spelling it Cantalopé), placing this group first among nine cultivated groups:

"Cantalopes, *Cucumis Melo*, var. *Cantalouensis*, are characterized by hard and more or less warty, scaly or rough skins, and they are often deeply furrowed or grooved. The name is derived from *Cantaluppi*, a former country seat of the Pope, near Rome, where these Melons were early brought from Armenia."

Vilmorin and Andrieux† use the word with much the same definition, but spell it Cantaloup. They say: "There are numerous classifications of melons. Of these we shall follow the simplest and most common one, which divides them into two groups of the Netted and the Cantaloup or Scabby-skinned melons." Nicholson‡ says: "The Cantaloup melon has a remarkably irregular surface, and both the skin and flesh are irregular in color." Funk and Wag-nalls § give a definition which is clear enough, but somewhat confusing when considered with those cited: "A variety of Muskmelon having a yellowish or pale green skin and reddish flesh." In connection with this definition they give a quotation from F. S. Cozzens || which bears directly on the discussion in hand. He says: "You call all kinds of melons Cantalopes in Philadelphia, but permit me to say that it is a local error." The definition of *The Century Dictionary* is as follows: "A variety of Muskmelon somewhat ellipsoidal in shape, ribbed, of a pale green or yellow color, and of a delicate flavor." *The International Dictionary* says: "A Muskmelon of several varieties, having when mature a yellowish skin and a flesh of reddish orange color." In *Murray's New English Dictionary* Cantaloup is defined as "a small, round, ribbed variety of muskmelon of a very delicate flavor."

Looking over these definitions one will be struck first by the general uselessness for scientific purposes of those given by the dictionaries. All of the dictionary definitions, especially that of *The Century Dictionary*, seem to lean to that description of fruit spoken of as coming from the seeds of northern seedsmen. On the other hand, the definitions of Nicholson, Vilmorin and Bailey substantially agree that a cantaloup is "a hard, and more or less warty, scaly or rough-skinned melon, often deeply furrowed or grooved," and quite definitely to be separated from the netted varieties of the Nutmeg type. It is worth remarking that these concurring authorities represent France, England and America. Unquestionably this definition ought to be accepted. Surely our horticulturists ought to agree on something and save to us this needful classificational term.

* Bailey: *Some Muskmelon Botany*, *American Gardening*, vol. xiv., p. 206.

† *The Vegetable Garden*, English edition, p. 3.

‡ *Dictionary of Gardening*, vol. II., p. 350.

§ *Standard Dictionary of the English Language*.

|| Cozzens, "Sparrowgrass Papers," ch. x., p. 134.

Regarding the spelling of this word there is also some doubt. The following are given: Cantaloupe, cantaloup, cantaleup, canteloup, canteloupe, cantalope, cantelope. Nicholson, Vilmorin and De Candolle, who follows Naudin, agree in spelling it cantaloup, and the weight of authority is certainly with this spelling. However, the spelling is not of so much importance to us as the correct use of the word.

F. A. Waugh.

New or Little-known Plants.

An Arizona Agave.

NO group of North American plants, with the exception, perhaps, of the Cacti, is more difficult than the Agaves to understand from specimens preserved in herbaria; and not much light is thrown upon these plants by the occasional isolated individuals which drag out a more or less miserable existence in the confinement of northern glass-houses. Much confusion naturally exists in the identification of plants which have been named for the most part from half-grown and often flowerless individuals in European gardens, and it is more than probable that the same species often appears in books under numerous names. There are no plants, however, that are so well suited to produce certain effects in the garden, especially in countries warm and dry enough to enable them to flourish in the open ground; and it is desirable from the horticultural as well as the botanical point of view that they should be studied under the most favorable conditions. These can only be found when all the forms of the genus planted side by side in some favorable region carefully selected for the purpose are studied by a competent botanist in all their stages of development. This is the only way the limits of the species can be determined and their synonymy satisfactorily settled. The astronomical observatories of some of our universities establish posts of observation in remote countries in order to study certain phenomena of the heavens under the best possible conditions, and the great scientific gardens of the world might in the same way increase their usefulness by establishing in regions of peculiar climates collections of certain groups of plants which cannot be studied in herbaria, or under the artificial conditions afforded by glass-houses. For example, all the Agaves, Dasylirions, Beaucarnias, Yuccas, Nolinias and Cacti would grow to perfection in a garden in southern New Mexico or Arizona, and in such a garden a good botanist would be able to learn, in the course of a few years, more about these plants than has ever been learned before. Agaves will never be known until this method is adopted, and Cacti certainly will not, for a Cactus in a pot rarely fruits, and often changes its appearance to a degree that makes it unrecognizable. For the satisfactory elucidation, therefore, of the flora of northern Mexico and the adjacent parts of the United States, where such plants are the conspicuous and most interesting features of the vegetation, a well-equipped local station is essential, and we hope some day to see this plan put into operation. In the mean time, labor expended in herbaria on the study of the plants we have mentioned is practically thrown away, as it can only be partial and never final.

There are not many species of Agave that grow spontaneously in the territory of the United States, but some of these are very beautiful. One of these species appears in the illustration on page 185 of this issue, made from a photograph, for which we are indebted to the courtesy of Mr. J. G. Lemmon, the well-known botanist of Oakland, California, who secured it on the foot-hills of the Huachuca Mountains, in southern Arizona, where this plant grows in large masses, usually along the upper edge of the mesa and below the forests of Live Oaks which clothe the lower slopes of the mountains and appear in the background of Mr. Lemmon's picture. We suppose the species to be *Agave Huachucensis* of Baker. It resembles, however, in

many respects the *Agave applanata* of Lemaire, and is not readily separable from Engelmann's *Agave Parryii*, which, in its young state at least, is not always distinguishable from the *Agave Palmeri* of the same author, or from a species of western Texas into which, perhaps, this plant also ranges. The name, however, is not important for our purpose, which is to call attention to a very beautiful plant which seems to be still little known in cultivation.

Plant Notes.

Cercis Canadensis.

THIS, our native Red Bud, is one of the most beautiful of the small trees which enliven with brilliant flowers the sylvan scenery of eastern North America. The flowers of all the species of *Cercis* are rosy pink, and are produced before the leaves in clusters or short racemes which cover the branches, and sometimes appear also on the trunks, so that when the trees are in flower they are masses of color. West of the Mississippi River, especially in some parts of Missouri, in the Indian Territory and southern Arkansas, the Red Bud is so abundant that it lights up the whole landscape during the month of April, when a journey through that region is a perfect delight for the lover of flowers. The beauty of this tree, too, is often heightened by the contrast of its rosy pink flowers with the pure white flowers of one of the Hawthorns, *Crataegus mollis*, and with those of the Flowering Dogwood, these trees frequently growing and blooming together.

The Red Bud, although it does not grow north of the valley of the Delaware River, in New Jersey, is perfectly hardy in New England; it is, moreover, an admirable garden-plant; and it can be used with the best possible effect against a dark background of conifers, which serves to bring out the beauty of its flowers. Although under favorable conditions it sometimes becomes a tree fifty feet high, the Red Bud begins to flower when only a few years old, and in good soil it grows with great rapidity.

The *Cercis Siliquastrum*, of southern Europe, has rather larger and more brilliant flowers, but, unfortunately, is not hardy in the northern states. A Chinese species, *Cercis Chinensis*, is a rather low shrub with large deep-colored flowers, which is often cultivated in the neighborhood of this city and Philadelphia, although farther north it is not hardy. This plant is often found here under the name of *Cercis Japonica* because it was first brought to this country from Japan, where it has long been a favorite garden-plant. The other species of *Cercis*, of which two are American, one Texan and the other Californian, are not in cultivation. But probably no other member of the genus is as valuable in our gardens as the eastern American species. It is one of a group of early-flowering small native trees which ought to be generally planted in our parks and large pleasure-grounds to brighten in early spring the borders of woods and give color and variety to the landscape at the time when most deciduous-leaved trees are bare of foliage and flowers are most appreciated. The Flowering Dogwood is one of these trees and the native Crab-apple is another; all the Hawthorns and the arborescent Viburnums can be used in this way.

All these trees harmonize perfectly when planted together, and never appear out of place in the composition of an American park picture. They belong to our flora, and so do not produce a discordant effect when they are used in the foreground of an American landscape, while an exotic plant equally beautiful in color and habit, like the Lilac, for example, gives, when used in this way, an effect of unrest and unsuitableness which, although difficult, perhaps, to explain, is, nevertheless, real. Fortunately our American flora is so rich and varied that the makers of park landscape who may desire to produce natural sylvan effects here are not obliged to have recourse to foreign lands for their material. Our woods can supply them with all the plants they need, and the best compositions for

study, and if they study Nature faithfully they should be able to produce the best results that are obtainable in this country. Exotic plants are often very beautiful, but the best of them, whether they come from Japan or China, Europe or the Orient, look strange and out of place in a truly American sylvan scene such as the park-maker, who makes the most of his opportunities, should try to produce for the weary workers in American cities.

SALIX CANDIDA.—As yet little attention seems to have been paid to the cultivation of Willows for the commercial value of their flowers. It is well known, however, that bunches of Willow-catkins are sold in great quantities in our cities every spring. The supply is usually drawn from wild natural plants, but it is possible that a well-managed plantation would yield a fair profit from soil that would be otherwise of little value. The earliest-flowering and largest and most showy-flowered varieties ought to be selected, of course, and for this purpose *Salix candida*

white tomentum which covers the ovaries, the latter being tipped by dark red stigmas. The twigs and the under surface of the leaves, and the upper surface when young, are covered by a dense white tomentum, giving the plant a grayish or hoary aspect, on which account the common name of Hoary Willow, or Sage Willow, has been given to it.

ANDROMEDA SPECIOSA.—A few well-flowered examples of this species were on sale in the leading florists' establishments of New York at Easter, and although these Andromedas are native shrubs found on borders of ponds all through the coast country, from Florida to North Carolina, they were novelties to most people who saw them. *A. speciosa* certainly rivals many of the finest Heaths when it is forced, with its pure white, bell-shaped flowers, sometimes half an inch long, borne on the naked branches formed the year before. When plants have been once forced, if they are kept in pots during the summer they will flower more freely the next year than they did the first season

Fig. 28.—A View of the Foot-hills of the Huachuca Mountains, Arizona, with *Agave huachucensis* in the foreground.—See page 184.

might not prove so profitable as some others, like *S. discolor* or *S. humilis*, compared with which it is a very small and much less vigorous plant. On account of the peculiar beauty of its blossoms, however, it is worth having in any collection of shrubs. Ordinarily, in its native cool bogs and swamp ground, this Willow is a straggling-stemmed plant from two to four or five feet high. Transferred to the drier ordinary ground of gardens it thrives very well, although not inclined to assume the neat, compact, bushy habit desired by many planters. The peculiar interest possessed by this species over its numerous congeners lies in the pretty pink or rosy red color of the stamens in the male plant. These stamens are tipped by red anthers, which, as they open to shed pollen, are changed to a bright light yellow color. The catkins are from half an inch to an inch in length and rather globose in outline when in full flower. On the female plants the catkins are more slender and they have a hoary white appearance, on account of the soft and dense

after they were taken from the open ground. But, although the natural home of this plant is in the south, it will survive the winters as far north as New England. Since the buds are formed in the autumn on the terminal shoots the wood does not always get well ripened in moist seasons, and, therefore, it is well in exposed situations to peg down the branches and cover them up. It is practically hardy, however, and one of the very best of our dwarf-flowering shrubs. It grows from two to four feet high, has a neat and compact habit, with shining light green leaves, which hold their color late into autumn, although they sometimes change to yellow, brown or purple. It was a popular plant in England early in the century, and we see complaints in the English horticultural papers that it has of late years been neglected, but it is doubtful whether it is any more rare in England than it is here. There is a variety known as *Pulverulenta*, which is a still more dwarf plant and somewhat neater, with bluish gray or chalky white leaves, which are covered with a dense bloom. Although *Andromedas* are

Ericaceous plants, peat soil is not necessary for either the species or the variety, and they will both do well in any soil which is not too dry. They propagate slowly from cuttings, the forced wood being best for this use; or they can be grown from seed, and the seedling plants will flower the third year.

Nymphaea Marliacea Ignea.—This new Water-lily, to judge from material sent by Mr. J. Brydon, is likely to be a first-rate addition to our hardy *Nymphaeas*. As noted in GARDEN AND FOREST last week, it is one of Monsieur Marliac's new series, and the plants noted are flowered here for the first time. It is superior to *N. flammea* and *N. Laydekeri* in size of flower and foliage, which is only slightly mottled. There is also a break away in the form of the flower and in the more numerous petals. The petals are a rich, deep magenta, self-colored, rather than a flame color or orange-red, as the name would indicate. The stamens, however, as in the other varieties, make a mass of orange. If the specimens shown are a fair indication, this variety, *Ignea*, out-classes *Flammea* in all respects, and would be the more generally valued of the two varieties.

Tecophilæa Cyanocrocus.—This bright little bulbous plant, which has survived several years in open borders near this city, seems to have found the last winter too severe for it in some gardens, for plants which were considered well-established have not appeared this spring. If this so-called Chilian Crocus has survived in the gardens of any of our readers we should be pleased to know something about its treatment. It has been classed among greenhouse bulbs, but we still have hopes that it may be useful in outdoor gardens with a little extra care. Perhaps it would be able to endure the cold if the bulbs were dried out thoroughly during the summer. The flower of *Tecophilæa cyanocrocus* is charming, standing erect, something like a Crocus, on a short scape, with six petals slightly spreading, about two inches long, and of the deepest gentian blue with white markings at the base. There are other species and garden forms of the plant, but the species of which we speak is hard to improve upon. Although introduced nearly twenty-five years ago it remains comparatively rare.

Cultural Department.

The Munson Grape Trellis.

THE propriety of using this term, the Munson trellis, has been questioned by a critic, who says that neither the trellis nor the system of training is distinct from other systems; that they are all Kniffin systems; that, at best, what goes by the name of the Munson system should be a variety of the Kniffin. It seems clear to me that the trellis and the training are distinct enough to bear special designations, and that the use of Mr. Munson's name is justified by the facts and sufficiently authorized by its recognition in Professor Bailey's *American Grape Training* and the last edition of the *Bushberg Catalogue*.

It may be well to explain, for those not intimate with this form of trellis, the construction used and advocated by Mr. T. V. Munson. According to this method the posts are made six feet high. At the top runs a cross-piece two feet long, at each end of which is fastened one of the wires of the trellis. Mr. Munson originally used two posts set in a V shape, with the tops two feet apart. The result is the same either way. Eight inches lower than the two side wires there is a third wire fastened to the posts. This brings the three wires into a very broad V shape. There are no other wires on the trellis.

The system of pruning, which forms a necessary part of the scheme, provides that one or two stems be brought up to the lower or middle wire, and that from these stems canes shall be run each way along this wire. From these canes the bearing shoots come at right angles, and naturally fall out over the top wires. Renewals are most easily made by spurring at the point on the lower wire, where the canes are given off from the main stem, though it is often a very easy matter to renew quite from the ground.

This system has been in use at the Oklahoma Experiment Station from the first, though that is not very long, and has given abundant satisfaction in most particulars. At the first glance those who are familiar with our severe winds, but not

with the working of this trellis, are much inclined to fear great damage from the whipping of the shoots, but, as a matter of fact, this serious difficulty is nearly overcome by the Munson trellis. It is one of the most vexing problems in the ordinary horizontal-arm training, but the increased height of the trellis does not increase the trouble. On the other hand, the peculiar position occupied by the growing wood gives it almost complete immunity. The green shoot is supported in two places near its base, while most of its length hangs free. Though it may swing in the wind, there is nothing against which it may strike, and so the damage is avoided.

Mr. Munson sets forth his ideas of the advantages of this system in Professor Bailey's *American Grape Training*, page 81. However, in our experience here, his summary is unsatisfactory. Some of the advantages which he claims do not seem to be peculiar to this system of training. Others are of slight importance. Those which are important ought to be more emphasized. In our experience the chief advantages of the system are (1) that it greatly reduces the damage from the wind; (2) that it reduces damage by heat reflection from the soil; (3) that it saves summer tying. The first of these advantages has already been explained. Regarding the second, it should be said that in this country, wherever bunches of fruit hang near the ground, they are usually more or less dried out by the excessive reflection of heat from the soil during hot summer days. The loss amounts to a great deal. A conservative estimate placed this loss at from ten to sixty per cent, through this country last season, and in some exceptional cases the crop was quite destroyed. With the fruit hanging five or six feet from the ground and overshadowed by a canopy of foliage at least two feet wide, this evil is evidently much mitigated. The young shoots do not need to be tied at all, but are left to swing freely from the support which is given at their bases. In most other systems summer tying is a considerable and expensive item. Some summer pruning usually has to be done, but this is much facilitated and probably reduced in absolute quantity by the Munson training.

Certain weak-growing varieties, like the well known Delaware, do not find this trellis adapted to their needs. Many other circumstances may decide against its use; but it is being widely adopted through this country, and there are many favorable reports from it in other states.

F. A. Waugh.

Kerosene Attachment for Knapsack Spray Pumps.

THE article of Professor Goff in GARDEN AND FOREST, April 10th, suggests a note on the improved form of a kerosene attachment to the knapsack sprayers which I have just perfected. A full description of this new apparatus is published in Bulletin No. 32 of the Mississippi Experiment Station, to which the reader is referred for any further details. Professor Goff made his first attachment to a Climax-pump, and in September of 1893 this attachment was given a trial at the station here. After ascertaining that the principle of the mechanical mixture of kerosene with water was correct, plans were submitted to the manufacturers and an attachment was made to the knapsack pumps.* For garden work, and, in fact, in most cases where we wish a mechanical mixture, excepting in orchards, the knapsack pump is undoubtedly superior to all others, and for this reason the attachment was made to this form of pump. The instrument reported upon by Mr. Marlatt, at the last meeting of the Association of Economic Entomologists, was this attachment to the knapsack pump, and his lack of success in no way affects the principle of the mechanical mixture. Previous to Mr. Marlatt's publication I had found two objections to the attachment: (1) The mixing of the kerosene and water in the pump when the stopcock is left open; and (2) the lack of graduation in the stopcock, so that the proportions in which the separate fluids were used could only be ascertained by first pumping the mixture into a graduated glass jar.

These objections, however, have been obviated in the new apparatus shown in the figure (see page 187). By means of two check valves at right angles to each other the kerosene and water are both permitted to go into the pump, but neither can go back, and so all possible mixture of the two liquids is prevented, except in the pump when operating. A brass gauge rod, which bends around to the side of the main tank, where it fits into notches on a gauge plate, is connected with the stopcock, the spring of the rod holding it firmly in place until charged by the operator. Each notch on the gauge-plate is plainly marked, so as to indicate the proportion which will be

* Bulletin No. 30, Mississippi Station.

pumped when the gauge-rod is placed in the different notches. Beginning at the top the notches read: $\frac{1}{10}$, $\frac{1}{9}$, $\frac{2}{10}$, $\frac{1}{8}$, $\frac{1}{7}$, $\frac{1}{6}$, $\frac{1}{5}$, $\frac{1}{4}$, $\frac{1}{3}$, $\frac{1}{2}$. That is, when the rod is at the bottom notch the stopcock is closed, and when at the top notch equal parts of kerosene and water will be pumped, and so on. The gauge-rod can be reached by the hand when operating, so that a change from one proportion to another can be readily made. Thus we have very nearly a perfect apparatus. Kerosene is a most valuable insecticide, and is always obtainable. In spite, however, of the oft-repeated statement that a perfect emulsion can be made by any intelligent farmer, the fact remains that nine-tenths of our farmers never really accomplish this, and this is why the emulsion has not been more generally successful.

We now know but little as to the number of injurious insects which can be successfully held in check by this kerosene attachment to the knapsack pump. Many entomologists assure me that they will give it a thorough trial during the coming season. For the benefit of any who wish to try this attachment, I would state that it is now being manufactured by the Deming Company, Salem, Ohio.

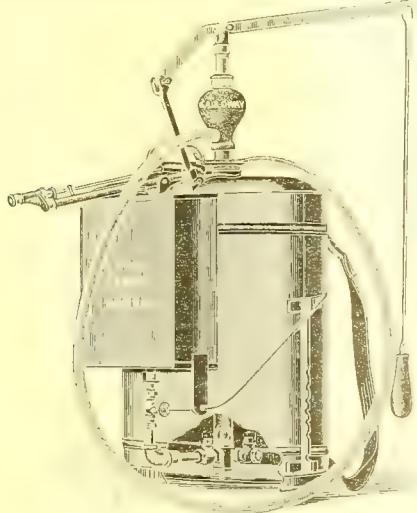

Fig. 29.—Improved Attachment for using Kerosene with Knapsack Sprayers.

Insect Pests.

NO one knows until he undertakes to cultivate the soil how many evils plants are heir to, and these seem to be on the increase. The insect pests, owing, presumably, to the survival of the fittest, seem to be more highly educated than of old, and it is only by continued watchfulness that successful crops can be grown. It seems to me, after a few years' study of this phase of garden routine, that insecticides are most profitably used as preventives. The process of fumigation is by no means the best method to adopt, especially with houses of mixed plants, such as are generally grown for gardens that exist for the pleasure of the owner, and not for commercial purposes. In the use of tobacco in its various forms as an insecticide we have a great advantage over European cultivators in that we can get an article good, cheap and pure in tobacco-stems fresh from the factory. That they lose much of their strength through keeping and exposure there is no doubt. If fumigation is necessary these stems should not be used, for there is too much heat generated for the amount of smoke given off. A cheap grade of damaged leaf tobacco has been found to be the best and cheapest for the purpose, for so little smoke to kill that it rarely has density or heat enough to burn delicate foliage. It is a long time now, however, since we used the smoke-pot, and this is due entirely to the scattering of the stems on the benches between the pots or on wire netting placed on the heating pipes. If used in the latter way, and damped occasionally, so as to give off a medicated vapor, hot water is almost as good as steam pipes as a vaporizing medium, and the stems will retain their strength for many weeks.

Those who have tried to grow Cinerarias and Calceolarias know how liable these are to the attacks of aphides, and how difficult it is to fumigate without damaging the plants. These plants furnish a striking proof that fumigation is not the best way to kill insect pests. It is barbarous to subject the plants to such an ordeal, to say nothing of the operator, when a sprinkling of stems around the pots, renewed two or three times during the season of growth, will quite clear them of insects, so that there is a real pleasure in growing the plants.

We have always had a great deal of trouble with what is known in common garden language as the Orchid thrips, a little white insect, barely visible to the naked eye, but which, before it is discovered, does great damage to the young foliage of plants. Cypripediums are happy hunting-grounds for these thrips, and there is no insecticide that I know that will check them except tobacco-stems liberally sprinkled between the plants. If badly affected it is well to sponge the foliage with an insecticide first to get rid of the older ones, and the young insects will be killed off as they hatch out. It is said that as the tobacco-stems decay a large amount of ammonia is given off into the atmosphere, producing a healthy green in the leaves, more especially of Orchids. I am of opinion that this is something more than a theory. By taking a bunch of tobacco-stems and damping them it will be found after fermentation sets in that a pronounced quantity of ammonia is given off into the atmosphere for the plants to breathe. While it might be possible to overdo the matter in the use of too much of the tobacco-stems at a time, I have never had this occur. If their use is not so plentiful as to cause an untidy look on the benches it is safe to say there need be no fear as to damage, and preventive measures are much cheaper than any others.

We have lately had for trial a new insecticide, known as Lemon oil; it is a preparation similar to that called Fir-tree oil, and acts in the same way when mixed with water, but we find that it is not so liable to do damage as the latter, and is of use for a greater variety of plants. There is no need to wash off the mixture from the roots of plants as it is said to be also a fertilizer of the soil.

Tobacco-dust is now put up by all dealers and is a most effectual remedy for aphides. This also is a fertilizer, and if it is necessary to give more than one dusting it will benefit the roots as well as kill the insects. There seems to be a great difference in the quality of this article as put up for sale. We were induced to buy a barrel of it once, the price being low when bought in bulk; this particular lot was practically worthless, and it is reasonable that pure tobacco-dust could not have been sold at the price paid. I have found that the coarser grades are the purest and the best to use.

A word should be said for that best of all insecticides, cold water with a good force behind it. There are few insects that can withstand this treatment, especially if the Stott sprayer is used. We have four of them in steady use, and plant-growing has been much simplified by this invention. When some means is devised for mixing the various insecticides with the water as it comes from the main, there will be little excuse for unhealthy insect-ridden plants in the garden. White scale insects on Orchids are usually very hard to eradicate, especially on Cattleyas, and these are often infested when brought in from their native woods. The Stott sprayer makes clean work, and does not injure even the young growing tips of the roots if used carefully. If the least trace of scale is noticed it is best to apply this cure at once, for it is surprising how rapidly this insect debilitates plants. It should, perhaps, be said that our water-pressure is over one hundred pounds as it comes from the main, but a much less force would be sufficient, though how little would be enough I am unable to say.

South Lancaster, Mass.

E. O. Orpet.

About Daffodils.

IT would be interesting to know which of the Spanish Daffodils are referred to by Mr. Orpet as not reliable in Massachusetts. The mountains of southern Europe, from Spain to Italy, are rich in Daffodils of many forms, and it might be expected that some of these would fail in other countries, although the cause of the failure might be something besides the rigor of our winters. Certainly *Narcissus major* and *N. minor* are as hardy as anything in the family, and many of the Ajax, or large trumpet section, which, though bearing fancy names, are collected and selected bulbs, bear witness to the general hardiness of the family. Outside of the Tazettas, which come from the lowlands, and the Bulbocodiums, which are mostly north African, the entire family is very hardy here and I can see no distinction in that respect between the species and the hybrids. White Daffodils are credited with being rather more delicate than the yellow kinds, but of these my experience is limited, having grown only *N. moschatus* and Mrs. J. B. Cannon, both of which hold their own with the other varieties, and the little white *N. triandrus* is quite as hardy and vigorous within its limits as *N. Emperor*. As the white of a *Narcissus*-flower is not necessarily due to lack of vigor, like the variegation of a leaf, there seems no reason why they should be weaker than plants of other colors. In the case of white *Narcissi*, which are not plentiful, and of other rare and expensive kinds, the trouble comes from the anxiety to do the very

best, so that they are placed in too rich soil, or in some other way they are coddled to death. A bad memory as to details of cost is a good thing in the garden, and with such a memory one is more likely to treat all his plants on rational principles, which means leaving them alone and trusting much to nature.

I understand that a moderate amount of well-rotted cow manure worked in the ground makes the best soil for Narcissi, and it is well, though not absolutely necessary, to set each bulb in an enveloping layer of sand. Owing to a lack of this or any other nutrient my bulbs do not throw very long stems, but I think the flowers are more purely colored than those which are better fed. Purity of color is of more importance to me than size or length of stem. Were space available I should move my Narcissi every second or third year to new ground, or to that on which some other plants had been grown, after manuring. As a matter of fact, if closely planted, they require such changes, if only to free them from crowded offsets. They will, however, live for years with little fertilizing and crowded to suffocation, and even among the roots of trees or plants through which they can scarcely force their leaves. I once found a colony of bulbs under a clump of perennial Phlox, which was at least three or four years old, and whose roots were so matted that it was necessary to cut them apart to extract the bulbs. They did not flower there, but as they were the double Poeticus they would probably not have flowered any way. This would indicate that plantings in the grass are perfectly safe. They certainly lead to satisfactory results, as the grass furnishes a charming foil at flowering-time. This practice, however, is scarcely to be recommended for small gardens. These, unfortunately, have their limitations, and among their limitations is the very unfortunate one that everything is too much in evidence or under one's glance. In a small garden one cannot get nice effects, like a glow of gold from Daffodils in the distance, or plant some of the little treasures deftly, so that one always finds them when in flower with a certain sense of discovery to heighten the pleasure. I wonder how many large pleasure-grounds there are in the United States which are planted with such natural art that the weary owner could find interest and instruction in every likely nook, shady corner or sunny slope, everywhere restful pictures, and nowhere any intrusion of work and evident expense. The current landscape practice seems to be the planting of masses of plants for great display of color, as if a person enjoyed being gorged even with beautiful colors. Masses of color have their uses if they are not too conspicuous or not so numerous that they intrude upon one from every point of view. But the charm of the garden is mostly found in the more modest pictures produced by some happy combination of form and coloring. Pictures there are often of which one only catches a hurried glance, yet they fill the eye and satisfy us with their beauty.

Elizabeth, N. J.

J. N. Gerard.

Plants for Bedding.

AS the season for bedding out is now fast approaching there is little time left for further propagation, but if the stock of such plants as Coleus, Ageratum, Alternanthera and other quickly rooting species is insufficient a few may yet be struck, and these will be found useful in places where small plants are required. Hardening off is a matter of the greatest importance for all of these plants, although it is often neglected. The work must be done gradually, or if the plants are suddenly exposed to outdoor conditions after being nursed up in a warm greenhouse they will receive a check from which it will take them weeks to recover. Where a house can be devoted to these plants alone the work will be greatly facilitated, as the temperature of the house can be gradually cooled down until full air is left on night and day. If a separate house is not possible, cold frames will have to be utilized. The plants will be quite safe in these any time after the first of May with a slight covering over the sashes on cold nights. One drawback to the frames is that they are only suitable for the smaller classes of plants. For large specimens, as Agaves, Yuccas, etc., space must be found in a cool house for a few weeks previous to their being set out, for, although seemingly robust, this class of plants is as apt to receive a check as a tender Coleus. The results of a chill, though not apparent at the time, would tell afterward in the discoloring and dropping of the bottom leaves. A sheltered corner should be selected, and all the plants placed in the open air at least ten days before they are intended to be planted, and some means devised whereby they can be slightly protected should the nights prove to be too cold. The time of planting must be regulated according to the hardihood of the plants used. For the more tender species, such as Coleus, Alternanthera, etc., the first of June is

soon enough to trust them in the open ground in this vicinity, but where a large amount of bedding has to be done it is often necessary to commence a little earlier.

Tarrytown, N. Y.

William Scott.

Notes from Baden-Baden.

AMONG Snowdrops I beg to mention *Galanthus Caucasicus grandis* as one of the very best; the color of the large flowers is the purest white, and healthy robust plants grow in any situation and any soil very evenly. *Colchicum Szovitsianum* and *C. luteum* deserve praise among the earliest harbingers of spring; the former has small bright pink flowers growing in bunches up to the number of twelve, and the latter is remarkable for its bright deep yellow flowers; I have raised a fine variety of it, the flowers of which are twice the size of the typical form. The early flowering *Hyacinthus ciliatus* (*Muscari azureum*) comes from the heights of Asia Minor in several distinct forms. Of these the varieties *Robustus* and *Amphibolis* are stronger growers, and the best of all is the variety *Freyianus*, the turquoise-blue of the spikes being very showy. *Chionodoxa Luciliae* is now coming on with pink and white flowered varieties, which are very pretty. A few years ago I introduced a variety of *Anemone blanda*, which I called *Scythinica*; it is a very distinct plant, its flowers being mostly of the purest white. It is quite a picture to see a clump of this in sunshine. *Fritillaria alpina* is a small but lovely species; the chocolate bells have a bright yellow rim which causes a beautiful contrast. All the above are quite hardy.

Baden-Baden.

Max Leichtlin.

Correspondence.

Fall Planting for Sweet Peas.

To the Editor of GARDEN AND FOREST:

Sir,—Do you consider it safe or desirable to plant Sweet Peas in the fall of the year? Will plants produced from autumn-sown seed have any superiority in vigor or in the size of the flowers over those planted in the spring? If autumn planting is desirable, at what time should the planting be made and how deep should the seed be planted?

Cambridge, Mass.

S.

Whether Sweet Peas can be successfully planted in autumn depends largely on the latitude. In the southern states fall planting is a necessity, for this is the only way to give the plants a cool soil in which to make a strong early root-growth. Coming farther north, fall planting is safe up to, perhaps, the latitude of Washington, where the chances are about equal between planting in late autumn and in February. In southern California Peas must be brought into bloom as early as February, although the nights are so cool there that they may be planted during any month in the year. The rule observed by the large seed-growers is to plant just ahead of the rainy season. Indeed, they have acres of volunteer Sweet Peas—that is, from seed which were scattered on the ground during the harvest, and forty-five miles south of San Francisco these volunteer plants are in bloom by the first of May, and often early in April.

Speaking for the northern latitudes of this country, I will say that I have never had or heard of any considerable success with planting Sweet Peas where the winters are severe. Certainly this practice has no advantage. Sweet Peas do not take kindly to forcing under glass, although the florists will get an apology for flowers considerably ahead of the regular reason. My attempts at outdoor forcing have not been encouraging. The month of May has enough chill in the air to hold back the growth and enable them to get strong roots.

It ought to be said that our Sweet Peas are not as hardy as those our grandmothers had. In improving the flowers the constitution of the plant has been refined a good deal. And then the seed is nearly all grown under milder conditions than our northern climate affords. California sends us the great bulk of this seed, and the English and French grown seed is, perhaps, less hardy still. These two facts—the higher development of the flower and the growing of the seed in a milder climate—have, in a measure, detracted from the old native hardiness of the plant, and, perhaps, it

accounts for the blight which now kills so many plants, and for the need we now have of more skillful cultivation, and both these conditions bear upon the subject of fall planting. No doubt, a little ingenuity may bring a short row into bloom a week earlier than the regular season, but it does not seem to me worth while for the ordinary amateur to pay for the extra effort. Fall planting will hasten the flowers very little, but a warm southern exposure, a break against the north wind, well-drained soil that will work early, and fertilizing material well mixed through it so as to be ready for immediate use, will help a great deal. I had a respectable exhibit of Sweet Peas at the Springfield Rose Show on the nineteenth of June last year, and my plants were then beginning to bloom abundantly. This was largely due to the preparation of the ground in autumn, and to liberal annual manuring by which easily digested food was ready for the plants as soon as they started. I am usually ready to exhibit Sweet Peas two or three weeks before the Massachusetts Horticultural Society fixes the date for the Sweet Pea Show.

I consider it a great advantage in Sweet Peas to grow slowly during the month of May. They are naturally thrifty plants and very easily take on a fast habit, in which case they run into rank growth of vine without a bloom. Early planting is a safeguard against this, so that the root-growth is made in the cool soil, while the plant grows slowly above ground all through May. Not until the first of June do we want them to make a very perceptible growth above ground, but then they ought to be pushing up at least a foot a week. Not until they make this rapid start should liquid-manure or soapsuds be applied. They are rank feeders and abundant drinkers, and after the tenth of June it is a joy to see them grow straight up six feet and send out a flower-stem at every joint of every branch.

Indian Orchard, Mass.

W. T. Hutchins.

Notes from West Virginia.

To the Editor of GARDEN AND FOREST :

Sir,—Of a dozen varieties of Japan Quinces that we have planted here the one called Mærtosii is the most beautiful. Its softly shaded blossoms of a lively carmine remain in bloom for many days after the flowers on the more common red one have faded. But it does not seem as robust as some other kinds, and last year, between the drought of summer and the extreme cold of winter, it had a hard struggle for existence, dying nearly down to the ground. This spring it has made good growth and sent up many shoots, but it will not bloom. The common-flowered red type, on the contrary, is blooming as profusely as usual. It is hard to get too many of these Quinces. Their compact growth, beautiful healthy foliage and profuse flowers make them useful in so many ways, as screens, as hedges, as groups and as individual specimens. A number of other garden-varieties besides Mærtosii have not bloomed this year, but Maule's Quince seems perfectly hardy. *Jasminum nudiflorum* has bloomed only on the lower branches, and on the ends of its pendulous shoots which sweep the ground, where a wind-heaped mass of Oak-leaves protected the buds.

There is one feature of the present season which makes it sadly different from any other spring in my memory, and this is the scarcity of birds. Usually at this time the grove and garden and the old orchard are jubilant with song from many sparrows, flocks of robins, numbers of blackbirds and blue-birds, redbirds, Carolina wrens and crested titmice. This year we have seen but one pair of robins on the place, and the other birds are proportionately few, except the blackbirds, and these are here in undiminished force. They must be among the hardiest of birds.

The extreme cold weather of the winter, which extended so far southward, must have overtaken the songsters in their winter retreats and slaughtered them by thousands. Even English sparrows, which I had considered proof against cyclones and blizzards, seem to have succumbed to the cold, as very few have ventured to invade our home-grounds this spring. This morning only one song-sparrow sang his matins under my window, and later a single white-throated sparrow has rendered at intervals his sweet monotonous chant, which seems to have more of pathos in it than usual.

Danske Dandridge.

Recent Publications.

Les Fleurs de Pleine Terre. Vilmorin-Andrieux & Co. Fourth edition. Paris, 1894.

More than thirty years have passed since the first edition of this work appeared. From that time until the appearance of this much enlarged edition the authors have lost no opportunity to improve and enlarge it, and in the fourth edition will be found a manual of hardy plants indispensable to every one interested in their cultivation who is master of the French language. The value of this work in its present form is much increased by a number of plans of gardens prepared for it by Monsieur Edward André, the distinguished landscape-gardener. In this handsome volume, which covers nearly fourteen hundred pages and is profusely and capitally illustrated, the student will find specific directions for raising annual and biennial plants and their subsequent cultivation, and directions for the cultivation of aquatics and hardy perennials. By far the largest part of the work, however, is devoted to an alphabetical list of the best hardy annuals and perennials, with illustrations of many of the most important species. An excellent and most useful addition to this edition is found in the second part in a calendar showing, first, the time when seeds of different plants should be sown, and when they should be transplanted into the garden, and their time of flowering arranged month by month.

Les Fleurs de Pleine Terre is not a mere compilation, like so many books of its class. In it are recorded the careful experiments and observations of a remarkable family of scientific men who for three generations have labored to elevate horticulture, and more, perhaps, than the members of any other family, have raised it to its present position among the arts.

Part nine of the first volume of the *Contributions of the United States National Herbarium* is devoted to a report made by Mr. J. N. Rose on a collection of plants gathered in the Mexican states of Sonora and Colima, by Dr. Edward Palmer in the years 1890-91. Dr. Palmer's collections in these years contained no less than eighty-two undescribed species, among them a *Capparis* from the mountains near Manzanillo, a compact shrub eight feet high; a new *Cratæra*, a tree forty feet high, with a trunk fourteen inches in diameter; an arborescent *Morisonia*; a new arborescent *Forchhameria*, a photograph of which serves as the frontispiece to this report; an arborescent *Zylosma*, a tree thirty feet high; a new *Zizyphus*, which Mr. Rose proposes to call *Zizyphus Mexicana*. The fruits of this tree are gathered by the Mexicans and sold in the markets, being used as a substitute for soap and specially valued for washing woolens. *Veatchia discolor*, first collected in Lower California and described by Bentham in the *Botany of the Voyage of the Sulphur*, was found by Dr. Palmer at Angeles Bay, where it is called Torate Blanco. The bark is shipped to Europe and is said to have valuable dyeing and tanning properties.

The collection contains two new species of *Coccolobis*, one of which, curiously enough, was found on the mountain sides near Manzanillo, the species of this genus being usually littoral plants growing very frequently with their roots in brackish water.

A Palm, doubtfully referred to *Cocos*, found on the shores across the bay from Manzanillo, is described as a tree one hundred feet high, with large and pinnate leaves. The nuts are used in making soap.

These recent collections of Dr. Palmer's only serve to emphasize the richness of the Mexican flora, which seems practically inexhaustible in undescribed species and still offers a most inviting field for the searchers of botanical novelties. Mr. Rose's report, which is illustrated with a number of plates of his new species, is one of the most important of recent contributions to descriptive botany made in the United States.

Notes.

Monsieur Edward André, the distinguished landscape-gardener, editor of the *Revue Horticole* and Chevalier of the Order of the Crown of Italy, has recently been promoted to the grade of officer in that Order in recognition of his services in improving and enlarging the public gardens of Rome.

For covering the walls of a lean-to greenhouse there are few things prettier than the blue and white Plumbagos, *P. capensis* and *P. capensis alba*. They look best when trained on wires strung about three or four inches from the wall, and if in fairly rich soil and otherwise encouraged to grow, they will soon make a most brilliant display of bloom.

Daffodils and early-flowering Tulips have just passed their best, and every one who has a garden should now determine to have an abundant supply of them another year. A dozen varieties of Narcissi will give examples of all the leading types, and they are now so cheap that for a few dollars one can have enough to cut an armful any morning and hardly miss them from the general outdoor display.

The Missouri Currant, *Ribes aureum*, which is found in all old gardens, has a rather straggling habit, but it is among the earliest shrubs to show its flowers, and these are of a singularly clear yellow color. The great value of this plant, however, lies in the delicious fragrance of its flowers. No other shrub at this season has an odor at once so pleasing and so penetrating, and it is well worth planting for this quality alone.

The proceedings of the American Carnation Society at its fourth annual meeting have been published in a neat pamphlet of eighty pages, which contains not only the papers and discussions, the essential parts of which we published at the time, but it includes the valuable report of the nomenclature committee, which gives the names of all the leading varieties of Carnations, new and old, together with such information as to the quality of each as could be gleaned from the replies to a thousand circulars of inquiry sent out to the leading growers of the country by the committee.

So far the spring auction sales of plants in this city have been very brisk, and an unusual variety of plants have been offered. Indeed, all the ordinary staple herbaceous plants can be had for glass houses or open ground with shrubs and climbers, both tender and hardy, and trees for orchards and for ornamental planting. A comparatively novel feature is the offering of small lots of plants packed in baskets, so that they can be carried away by hand. This enables persons who only want a few plants to buy directly, so that practically a retail trade is carried on at auction.

The taste for the cultivation of Orchids is shown by the works devoted to these plants, which are constantly appearing. The last to reach us is entitled *Les Orchidées Exotiques et leur Culture en Europe*, a book of a thousand pages and nearly one hundred and fifty illustrations, by Lucien Linden, assisted by A. Coaniaux and G. Grignan. Botanical classification, the physiology of Orchids, their natural habitat, their cultivation under glass, importations and hybridization, are some of the subjects treated in this voluminous and comprehensive work. Some idea of the importance of Orchids as garden-plants can be obtained from the chapter devoted to their bibliography, which, without probably aiming to be exhaustive, occupies seven closely printed pages.

The Rhododendrons and other broad-leaved evergreens in the parks of this city and Brooklyn suffered very seriously from the trying winter. More than four hundred Rhododendrons were killed outright in Prospect Park, and in Central Park the destruction was almost as great, but the great mass of these plants in the extreme northern end of the park on a cold rocky slope facing the north came through without any injury whatever. The beauty and healthfulness of this group is a good illustration of the fact that these plants are not so much injured by cold as they are by the sun. Among the coniferous evergreens the Retinisporas were most badly damaged.

Two or three unusually warm days have had the effect of hurrying forward the flowers of the Sugar Maple, and for a few days past these trees have been the most conspicuous and beautiful objects in the landscape near this city. Whether standing alone or in a wood where the other trees show few signs of flowers or foliage, each separate tree looks like a soft cloud of lightest yellow, which is fairly luminous in full sunshine. In years when the weather is comparatively cool at

flowering-time these trees do not make such a striking display, because, when the flowers appear more slowly, they are accompanied by the leaves of the tree, and, although they are always beautiful, the effect is heavier, or, at least, it is not so airy as when the flowers appear alone.

More apples were exported in the season just ended than in any previous year, not excepting the banner season of 1891-92, when 1,450,336 barrels left this country for European ports. Nearly two million, or about 1,946,139, barrels of apples were forwarded to Europe from Canada and the United States this season. Prices abroad have been satisfactory to the shippers throughout the entire season, which began earlier than usual, owing to the failure of European apple crops. Golden Russets of good quality recently brought \$4.25 to \$4.75 at the wholesale auction sales in Liverpool for a barrel holding 140 pounds, and California Newtown Pippins, \$3.00 a box of forty pounds, net weight. There are but few apples in the wholesale markets in this city, the entire receipts for last week being quoted as 3,719 barrels. Since September 502,879 barrels have been sold here, against 225,221 barrels during the same term a year ago. The few Baldwins now offered command \$3.75 to \$4.50 a barrel; Northern Spies, which are even more scarce, \$3.00 to \$5.00, and Ben Davis \$4.50 to \$5.00. A few barrels of Newtown Pippins are coming from the Hudson River district, and Golden and Roxbury Russets, the latter costing as much as \$4.25 a barrel, make up the bulk of the stock on hand.

The literature of spraying has received another addition in a bulletin prepared by Mr. E. G. Lodeman, of the Cornell Experiment Station, which gives a report of experiments with apples, quinces and plums, but, after all that has been said, very little that is absolutely new can be expected. It seems to be established that the arsenites and the copper compounds will often save crops of fruit from insects and fungi when they are properly applied. The fact is also emphasized in this bulletin that spraying sometimes does little good, which means that orchards suffer from other causes than disease and insect pests. Spraying will not bring a crop of fruit when there is no food for the trees or when it is not in a form that is available. This means that fruit-growers should be as persistent in applying fertilizers and cultivating the soil as they are in the use of remedies against insects and fungi. Some of the results set forth in Mr. Lodeman's bulletin are that power sprayers are unsatisfactory with large trees because they do not throw the liquid far enough or enough of it, and, therefore, hand pumps must be relied upon in orchards, while power sprayers can be used to advantage in vineyards and among low-growing plants. Three gallons of Bordeaux mixture are needed to a tree twenty-five years old. To be effective against the codling moth Paris green must be applied immediately after the blossoms fall. Leaf-spot and cracking of the quince, the apple-scab, the shot-hole fungus of plums and cherries, and the fruit rot of plums and peaches, can all be held in check by the proper use of the Bordeaux mixture.

The Black Tartarian cherries now coming from California are larger and of a deeper color than those seen here a week ago, but they are not yet perfectly colored nor of full size. They come in box lots, without ice, and bear the journey of three thousand miles and the changes of weather on the road very well. It is expected that cherries will arrive by the car-load in refrigerator cars by the end of this week. As many as one hundred car-loads of California oranges, mostly seedlings, will reach eastern markets during this week. California grape-fruits of large size are offered at \$6.00 a box by wholesale dealers, but find slow sale, since they are light and comparatively juiceless. The smaller and thinner-skinned Jamaica pome-llos of really excellent quality bring \$7.50 a box. The Jamaica orange season is now ended, though a limited quantity of new fruit known as the spring cutting will come from that island a little later on. The last Havana oranges have arrived, and the stock of this fruit still on hand is bringing \$3.50 a barrel. More than 16,000 barrels of pineapples were landed here during last week, and on Monday alone some 14,000 barrels of this fruit were unloaded on the docks. The season for Cuba pineapples is now at its height, and in a fortnight they will come from the Bahamas and Key West. The Florida supply will be hardly a third as large as last year, nearly all the plants in the central part of the state having been frozen. Prices at wholesale range from \$4.00 to \$16.00 a hundred. A few boxes of wild oranges from Jamaica, known in the trade as Bitter Fruit, are seen in the wholesale stores. These are used solely for marmalade, and sell to canners at \$2.00 a box. Catawba grapes, held over winter in cold storage, are still occasionally seen, a box containing two and a half pounds costing thirty-five cents.

American Forest-trees in Spring.

THIS is the season when we especially realize how inadequate ordinary botanical descriptions are to give any distinct idea of the appearance of our forest-trees. Even when good figures of the flowers and the leaves are presented, and when we have access to dried specimens, there is nothing to indicate the wonderful transformation which takes place every day in early spring as soon as growth begins. Even in coniferous evergreens with the first genial weather the leaves warm into a deeper color, the surfaces become more smooth and reflect more light, the bud-scales take on tints of pink and brown, and the new shoots have a gray and silvery appearance which entirely changes the general aspect of the tree. But the variation in color and form manifested by our deciduous trees is much greater. The autumn colors of our woods have long been celebrated, but as a matter of fact our forest-trees in May take on a wider range of color than they do in autumn, tints which are not so striking and gorgeous, but which are more delicate and refined.

The display of soft color begins even before the buds have noticeably swollen. The bark of the Birch-twigs turns to a richer brown, the Willow glows with a clearer yellow, and as the spray of each tree swells with the rising sap, its peculiar tint is intensified, so that long before a leaf is seen the trees are enveloped with a delicately tinted and elusive mist, which cannot be described in words, but which is the visible prophecy of approaching spring to every observing eye. Indeed, this spring halo hovers over every forest and thicket as one of the most mysterious and beautiful spectacles of all the year, although it is evanescent and almost spiritual in quality. But when the buds begin to open and release the unfolding leaves the entire aspect of the woods changes every day, and as these transformations follow each other all through the month of May, our northern forests display a matchless variety of form and of harmonious color.

The scarlet flowers and fruits of the Red Maple, the snowy blossoms of the Amelanchiers, the pink of the Red Buds, and a little later on the blossoms of Dogwood, Plums and Wild Apples, are what we first think of as the conspicuous features of our spring forests. But, while these occasional masses of flowers help to emphasize the beauty

of the woods, it is the variety and richness of the foliage which furnish their highest charm. Besides the rich tints of the young leaves, the scales of the leaf-buds in many trees assume bright colors, and in some cases, as in that of the Hickories, they grow to the size of full-grown leaves before they fall. The leaf-buds of the Amelanchier, for instance, though not as striking as the flowers, are quite as beautiful. The bright bud-scales of the Beech, whose rich color is intensified by the contrast of the delicate green of its young leaves, are as handsome as any flower could be. The long yellow-green catkins of the Birches, the bright red of the young growth of the Stag-horn Sumachs, the airy grace of the first foliage of the Hornbeams, not to speak of the tints of the Sassafras, the Wild Cherry and many other trees, make combinations which can hardly be appreciated by those who live in countries where the forests are made up of half a dozen species. And when, in addition to this richness and variety of color, we recall the fact that this panorama changes entirely every day and that each tree takes on a new aspect as its leaves thicken and its colors vary, we then realize how rich and multifrom is the beauty of our forests in the early year.

This marvel of variety is better appreciated if we examine one particular class of trees. The Oaks, for example, are especially interesting because they form so large a portion of our forests, and they show such a wide range in color and in habit at this season. About a year ago we published an article by Mr. E. J. Hill, which gave, in some detail, an account of the expression of a dozen species of Oaks which are indigenous to the vicinity of Chicago, and this record of a careful observer is of uncommon interest, as it sets forth the fact that almost every tree has a marked individuality. This is not only because the young leaves have different colors, those of the Black Oak, for example, being red, and some of them nearly scarlet, while the young leaves of the Scarlet Oak are at first quite purple, changing to light green, and those of the White Oak stained with purple and pink. The leaves vary quite as much in texture; some of them are whitened with a dense, though pale, tomentum; others are smooth or only slightly hairy, while others still are quite smooth and glossy. In some species the young leaves are so deeply cut as to give them a feathery look; in others the leaves are crowded at the ends of the branchlets in tufts; in some the petioles are long and flexible, so that the pendent leaves are easily stirred in the wind; in others they are shorter and more sturdy, so that the leaves stand out stiffly from the ends of the branches. In the different species the twigs are stained with different colors and covered with more or less down, which ranges in tint from dark russet to light gray; in some these twigs are short and stubby, and in others they quickly grow out long and slender, which gives an entirely different aspect to the tree as it is stirred by the wind. In every case the shape, and color, and attitude, and texture of the leaf are quite distinct, so that each tree has its own special appearance in sunshine and in shade, enabling any one who is familiar with them to distinguish the species quite readily at a distance in the season when they are putting forth their leaves.

The purpose of this article, however, is not to attempt an elaborate description of the appearance of any one of our forest-trees or any class of them, but rather to direct attention to one phase of the beauty of our American landscape which has been comparatively neglected. Every autumn the railroad and steamship companies of this city advertise excursions up the Hudson and to various points in neighboring states, in order to give an opportunity for seeing the glowing colors of our forests at that season. But one who spends half a day in early May in Central Park or in Prospect Park will see a picture equally rich in color and of even more varied interest. At every season our forests present spectacles of great diversity owing to the large number of tree species which they contain, but since every one of these trees changes its appearance every day as the leaves

unfold, there is an endless number of combinations for those who are on the alert to watch them. At this season, too, the air is full of an opaline haze which softens every color and smooths every rugged line, so that the prospect from any eminence which commands a forest-view is one to be studied and remembered. One who fails to note these daily transformations in our individual trees and in our woodlands loses every year one of the most characteristic and impressive phases of American landscape beauty.

Parks, Parkways and Pleasure-grounds.—I.

THIS is the title of an instructive paper in the May number of the *Engineering Magazine*, by Mr. Frederick Law Olmsted, who has had a more varied experience in designing municipal pleasure-grounds than any man in America, and, perhaps, than any man in the world. Of course, different kinds of recreation call for different types of public pleasure-grounds, and Mr. Olmsted names the plaza or formal tree-shaded promenade as the simplest. Such works are practically out-of-door halls, where the people may meet in a social way, and their use is better understood in southern Europe and Spanish America than in our country. More necessary still are open-air nurseries or playgrounds, which ought to be provided in every crowded neighborhood, where mothers and small children may find opportunity to rest and sleep and play in the open air. Playgrounds for youth or open-air gymnasias can be more remote from the crowded wards of the city. Then there are luxuries, like flower gardens, which the city ought to provide, but not until after the more essential kinds of public grounds have been secured. Of course, all these promenades, concert-grounds, nurseries, playgrounds and gardens can be combined in one way or another, and they need take a comparatively small space of the city area. But, besides these is the park proper, which is intended to provide rural scenery as a source of refreshment for townspeople. The wealthy seek change of scene in travel, but those who cannot afford this ought to have available natural scenery, and to furnish this a considerable area of land is needed. In our large cities it requires too much time to get into the country, and entrance to the fields is forbidden when it is reached, and, therefore, it becomes necessary for every large city to secure for the use and enjoyment of its people such neighboring fields and woods, pond-sides and river-banks, valleys and hills as may be made to present fine scenery of one kind or another.

On the subject of governing parks of this kind, Mr. Olmsted says :

The providing and managing of reservations of scenery is the highest function and most difficult task of the commissioners or directors of park works. Public squares, gardens, playgrounds and promenades may be well or badly constructed, but no questions are likely to arise in connection therewith which are beyond the comprehension of the ordinary man of affairs. If scenic parks, on the other hand, are to be well placed, well bounded, well arranged, and, above all, well preserved, the directors of the work need to be more than ordinary men. Real-estate dealers must, necessarily, be excluded from the management; politicians, also, if the work is to run smoothly. The work is not purely executive, like the work of directing sewer construction or street cleaning, which may best be done by single responsible chiefs. The direction of park works may probably best rest with a small body of cultivated men, public-spirited enough to serve without pay, who should regard themselves and be regarded as a board of trustees, and who, as such, should make it their first duty to hand down unharmed from one generation to the next the treasure of scenery which the city has placed in their care. Public libraries and public art museums are created and managed by boards of trustees. For similar reasons public parks should be similarly governed.

A landscape park requires, more than most works of men, continuity of management. Its perfecting is a slow process. Its directors must thoroughly apprehend the fact that the beauty of its landscape is all that justifies the existence of a large public open space in the midst, or even on the immediate borders, of

a town; and they must see to it that each newly-appointed member of the governing body shall be grounded in this truth. Holding to the supreme value of fine scenery, they will take pains to subordinate every necessary construction, and to perfect the essence of the park, which is its landscape, before elaborating details or accessories, such as sculptured gates or gilded fountains, however appropriately or beautifully they may be designed. As trustees of park scenery they will be especially watchful to prevent injury thereto from the intrusion of incongruous or obtrusive structures, statues, gardens (whether floral, botanic or zoölogic), speedways or any other instruments of special modes of recreation, however desirable such may be in their proper place. If men can be found to thus serve cities as trustees of scenic or rural parks they will assuredly be entirely competent to serve at the same time as providers and guardians of those smaller and more numerous urban spaces in which every means of recreation, excepting scenery, may best be provided.

In selecting park sites and boundaries the first problem usually is to choose from the lands sufficiently vacant or cheap to be considered, (1) those reasonably accessible and moderately large tracts which are capable of presenting agreeable secluded scenery, and (2) those easily accessible or intervening small tracts which may most cheaply be adapted to serve as local playgrounds or the like. A visit and report from a professional park designer will prove valuable, even at this earliest stage of operations. Grounds of the local playground class may safely be selected in accordance with considerations of cheapness and a reasonably equitable distribution, but the wise selection of even small landscape-parks requires much careful study. It is desirable that a city's parks of this class should present scenery of differing types. It is desirable that the boundaries of each should be so placed as to include all essential elements of the local scenery and to produce the utmost possible seclusion and sense of indefinite extent, as well as to make it possible to build boundary roads or streets upon good lines and fair grades. Public grounds of every class are best bounded by streets; otherwise, there is no means of insuring the desirable fronting of buildings toward the public domain. In spite of a common popular prejudice to the contrary, it will generally be found that concave, rather than convex, portions of the earth's surface are to be preferred for park sites. If the course of brooks, streams or rivers can be included in parks, or in strips of public land connecting park with park, or park with town, several advantages will be secured at one stroke. The natural surface-drainage channels will be retained under public control where they belong; they will be surely defended from pollution; their banks will offer agreeable public promenades; while the adjacent boundary roads, one on either hand, will furnish the contiguous building land with an attractive frontage. Where such stream-including strips are broad enough to permit the opening of a distinctively pleasure drive entirely separate from the boundary roads, the ground should be classed as a park. Where the boundary roads are the only roads, the whole strip is properly called a parkway; and this name is retained even when the space between the boundary roads is reduced to lowest terms and becomes nothing more than a shaded green ribbon, devoted, perhaps, to the separate use of the otherwise dangerous electric cars. In other words, parkways, like parks, may be absolutely formal or strikingly picturesque, according to circumstances. Both will generally be formal when they occupy confined urban spaces bounded by dominating buildings. Both will generally become picturesque as soon as, or wherever, opportunity offers.

After adequate squares and playgrounds, two or three local landscape parks, and the most necessary connecting parkways shall have been provided, it may next be advisable to secure one or more large parks, or even one or more reservations of remoter and wilder lands. In a city of five hundred thousand inhabitants a park of five hundred acres, however judiciously located, is soon so much frequented as necessarily to lose much of its rurality; in other words, much of its special power to refresh and charm. The necessarily broad roads, the numerous footways, the swarms of carriages and people, all call to mind the town, and in a measure offset the good effect of the park scenery. It is then that it becomes advisable to go still further afield, in order to acquire and hold in reserve additional domains of scenery, such as Boston has lately acquired in the Blue Hills and the Middlesex Fells. In selecting such domains, however, no new principles come into play. As in selecting sites for parks, so here it is always to be borne in mind that provision and preservation of scenery is the purpose held in view, and that demarcation of acquired lands is to be determined accordingly.

Botanical Notes from Texas.—XXV.

WAYSIDE FLOWERS.—The spreading *Senebiera didyma* is certainly entitled to this name. In the cities of the state, and as far north as Little Rock, Arkansas, it is very common everywhere, underfoot along the streets and often attempting to climb the exposed brick walls of buildings. The species may readily be detected by its variously cut leaves, the strong and almost fetid volatile oil which it exhales, and by the twin pods which justify its individual name.

The East Indian Strawberry, *Fragaria Indica*, now commonly introduced into the more eastern Gulf states, is often to be seen in the streets of Texas cities. It has a large foliaceous calyx, yellow flowers, and bears insipid dark red fruit. In riding through southern Arkansas, I heard at a railway station enterprising boys shouting "fine ripe strawberries"; they were selling this species for the genuine article. After the boys had received their ten cents a box for the berries and the train had moved on, the profanity of the travelers who tested the fruit did the sellers no harm. All the Texas species of *Tissa* delight to be literally in the way and where they are most liable to be trodden upon. We have several other small Pinks which delight in human society, and they are more common in cities than in the country. *Mollugo verticillata*, Carpet-weed, is far more abundant along railways and wagon-roads and in streets than elsewhere. Its more rare relative, *M. Cerviana*, is sure to develop the same living ways.

Monolepis chenopodioides is another plant which, though called a desert plant, is common by the wayside in many of the cities of Texas, from Galveston northward and westward. It belongs to the Chenopods, most of which are denizens of towns and cultivated fields, as much as is the species once thought to be peculiar in that respect, and so named *Chenopodium urbicum*. *C. ambrosioides*, Mexican Tea, and its variety, *Anthelminticum*, Wormseed, are seldom to be seen outside of towns and cities. The so far as known exclusively Texan *Galactia*, *G. heterophylla*, wherever I have seen it, takes readily to town life, or clings with tenacity to its old ways of living in spite of town building. Hundreds of plants of this species grow in Llano in the streets, close to the wagon tracks, and often on the ridges between the tracks.

The misnamed California "Clovers," Medics, humble yellow-flowered relatives of Alfalfa, are oftener found in cities and along railways than elsewhere. The species with purple-spotted leaves is rarer than that with unmarked and smaller leaflets. Both species may, in fruit, be easily distinguished from true Clovers by their tightly coiled bristly pods. The Geranium-like *Erodium cicutarium*, *Alfilaria*, Pin Clover, another misnomer, is cultivated sometimes for forage. I have only seen it between the ties on railways. *E. macrophyllum* grows at Austin in the state-house grounds. *E. Texanum* is common south-westward, especially around San Marcos.

Some Grasses have assumed the same ways of living as their supposed higher and more aristocratic plant neighbors. Common Buffalo Grass is not so near extinction as some of its botanical friends have intimated. The paucity of the seed-bearing form may largely tend to keep the species from literal dissemination, but the stoloniferous way of growing that both forms possess will keep it common. It is creeping along railways everywhere within its extended range, from Galveston Island to Manitoba, and from eastern Kansas to the mountains. The species is more liable to become a sharp competitor of Bermuda Grass than to become exterminated. The handsome *Oplismenus setarius* shows the same tendency as Buffalo Grass, and leaves woods for railways when an opportunity presents itself. This grass is sometimes utilized for "hanging basket" culture, for which it is well adapted. Its stems may become three to four feet long. It grows from Louisiana to San Antonio Springs, and nearly across eastern Texas from the Gulf to the Red River, so it is easily attainable.

The philosophy of the ways of living that town and wayside plants have adopted may rest in the fact that most of these are creeping or, at least, prostrate plants. Pressing them in close contact with the ground would enable them to root more readily, and so to grow and spread more rapidly. The so-called introduced useful plants are more common in cities, as they usually have their seeds first scattered there. Botanists soon learn that towns, cemeteries, and especially railways, afford excellent fields for the study and collection of plants. The broken ground there, the seeds scattered by human beings or live stock as they ride along, and the usually fenced condition of railways, allow plants to remain there in security, while they are destroyed in the pastures. There also introduced plants find lodgment and protection.

Corsicana, Tex.

E. N. Plank.

The Saguenay Region.—II.

AUGUST is the month for the ripening of blueberries in this latitude. They grow in the greatest profusion on the rocky ridges and in the Pine-lands. Two kinds were noticed, the Dwarf Blueberry, *Vaccinium Pennsylvanicum*, and the Canada Blueberry. Both mature here at essentially the same time, though the two differ in this respect by several weeks farther south. In the vicinity of Caicago the Dwarf Blueberry is the earliest of all, ripening the last of June, and the Canada Blueberry comes on three or four weeks afterward. This difference in time lessens as we go northward. The berries were large and of the best quality. They hang upon the bushes till all are ripe, and remain plump and fresh until the early frost overtakes them. The two kinds were frequently so intermingled as to make it difficult to decide whether there was any choice of soil or habitat by either species, as is generally the case in other localities where I have seen them, the Dwarf Blueberry taking to dry and rocky land, and the Canada Blueberry to damper conditions. The blueberry season makes a kind of harvest-time for the farmers and villagers, who go out to gather them, the entire household often taking part in the work. Few but French Canadians live here permanently, and they are mostly poor or with small holdings. The sale of the Bluels, as they call the berries, supplements their scanty incomes, although they dispose of them at one cent a quart. A lady who had been at St. Alphonse for some seasons said that it was looked upon as unprecedented when thirty cents were obtained for twenty-five quarts. The great abundance of the berries and comparative absence of green fruit enable the pickers to gather them with rapidity, and a skillful hand will take from one to two bushels a day. They are partly sold to canning establishments, run by persons who come in for the season, and are partly sent away in boxes. As they chiefly grow on land useless for tillage, and the supply is so great that a large percentage of the berries must annually go to waste, they provide a source of revenue for an indefinite time to come.

Another plant of the Heath family furnishes a product for home consumption, the Cowberry, or Mountain Cranberry, *Vaccinium Vitis-Idaea*. It is used like the common cranberry. Before I had found them in the fields some were handed me by a farmer in whose house I happened to be. Finding they were not the common cranberry, I inquired where they grew, and subsequently came across them on the rocks. The shining leaves and bright red berries, borne a little above the surface of the ground on short stems, were always an attractive sight. The fair round fruit suggested the propriety of one of the common names they have among the French Canadians, Pommes de Terre, Earth Apples, which seems even more appropriate than when applied to the common potato. They are also known to the people by the same name they bear among the French of the Old World, Aigrelles ponctuées, or Dotted Bilberries, since the under surface of the leaves is sprinkled with blackish points. The Cowberry was sometimes associated with another slender vine or prostrate shrub, the

Crowberry, *Empetrum nigrum*. I found this in the greatest quantities on the rocks along the St. Lawrence and the Saguenay in the vicinity of Tadousac. The blackberries contrast strongly in color with the red globes of the cowberry, and patches of the two growing together on the rocks formed charming little fruit gardens. The berries, which the Canadians call Camarines, are used in the same way as the cowberries, although they seem less serviceable and rather seedy with their eight or nine hard nutlets, though the flesh has an agreeable acid taste. Still another low plant was sometimes found in the same localities, or even mixed with these where there is a thin bed of peat-mold in the hollows of the rocks. I refer to *Comandra livida*. Its leaves resemble those of our common *C. umbellata*, but are generally larger. The fruit looks quite different, and is rather handsome. The woody roots or stems creep among the moss, sending up herbaceous stems about six inches high, which bear one or more red berries in the axils of the leaves. These are very ornamental when seen among the smooth and thickish oval leaves.

These peat mosses on the rocks, or nearly up to the summit of some of the ridges, were a frequent cause of surprise. They brought plants of very different habits into close proximity. A hollow space to catch the rainfall, or into which water ran from neighboring rocks a little higher, seemed all that was needful for Sphagnum and its characteristic plants. It was but a step from a barren, glaciated surface of rock, or one sprinkled with a few plants, to one of these beds of peat, where one would be in the midst of *Cassandra calyculata*, *Ledum* or some kindred growth. The moist air and frequent showers or fogs did not often permit the hollows to become entirely dry, and the spongy sphagnum well served its purpose of a mulch for such plants as root in the soil formed by its decay.

Ledum latifolium and *Kalmia latifolia* were not confined to such places, but were common in sandy land. Though mostly found in fruit, some were seen in flower as late as the end of August. *Cornus Canadensis* was not infrequent in flower but a few days before. Besides the Ericaceous plants that have been mentioned, the other more noticeable ones were *Epigaea repens*, *Chimaphila umbellata*, *Gaultheria procumbens*, *Pyrola elliptica* and *P. secunda*. *Mono-tropa Hypopitis* was frequent in the Hemlock woods at Tadousac. Trailing over the ground in the deep shade of evergreens was the slender *Linnaea borealis*. A familiar shrub, common about the Great Lakes in the sand, *Shepherdia Canadensis*, here grew upon the rocks. In the peat bogs and Tamarack swamps the persistent calyces and expanded style of the Pitcher-plant were still conspicuous, simulating some deep purple flower.

The rocks were often enlivened by the presence of the blue bells of *Campanula rotundifolia*, which sprang from any bit of soil where it could gain a foothold. It usually appeared under that form which gives it its specific name, with plenty of roundish leaves growing at the base of stems. Though the taller form with linear leaves, the variety *Langsdorffiana*, is the one most frequently seen in the vicinity of Chicago, the typical form with the round leaves grows upon the steep sides of sand-hills in the Pine-barrens. Similar conditions of growth have brought about quite the same results, and produced the features which are more habitual to it in its rocky home, for it seems to make but little difference whether it roots in the scanty soil of some rock crevice or in rock that has been ground to fine silicious sand and piled by the wind into a dune, and fixed in place by a scanty growth of shrubs and trees. This is a feature shown by several plants which have gained a lodgment on the dunes, but are in other places known as denizens of the rocks. One of these is the Pale *Corydalis*, *C. glauca*. It needs a more generous supply of soil than the Harebell, being a plant of larger growth. It was specially frequent on the rocky inclines facing Ha-ha Bay, where its smooth glaucous stems and yellow-tipped purplish petals formed a dainty combination amid the general barrenness. The usual wild Strawberry of the region

was *Fragaria vesca*, well marked by long conical berries, shaped like a sugar-loaf, and by its superficial akenes. Here, as well as in other places where I have met with it, the plant seems most at home in its typical form among the rocks, and more common in the northern latitudes.

Chicago, Ill.

New or Little-known Plants.

Miltonia vexillaria, "Fairy Queen."

THIS chaste and beautiful variety has now been in flower for three weeks, and the photograph, which was taken a fortnight ago and is reproduced on page 195, does not do it justice. The plant is growing in a seven-inch pan, having four leading growths, carrying nine spikes and fifty-three flowers, each flower measuring more than three and a half inches in length by three inches in breadth. The lip is of the purest white, with a rich lemon crest; the sepals and petals are broad and overlapping—sepals white, and the petals white slightly and faintly tinged with pink at the base on their first opening, but gradually becoming pure white. Several forms of so-called white Miltonias have been introduced, such as *Cobbiana*, *Albescens*, *Alba*, etc., but "Fairy Queen" stands to-day unquestioned, and justly so, as the only pure form yet introduced.

This plant was secured four years ago, having at that time two bulbs and one lead. It has been grown with our other Miltonias in a temperature of sixty degrees by day and fifty-five degrees at night, but during very severe weather we allow the temperature to fall a trifle lower. We grow them at the west end of our *Odontoglossum*-house all the year round, and every *Miltonia* is just as perfect as the one shown in the illustration. After the flowering season we keep them partially at a so-called rest, not giving them so much water at the roots, but maintaining plenty of atmospheric moisture. When they commence to grow and young roots are emitted from the base of the growth they are overhauled and such plants as require repotting are attended to. The best potting material is made of equal parts of good fibrous peat or Fern root, with the fine part sifted out, and fresh sphagnum picked in small pieces, with finely sifted dry cow-manure sprinkled through the whole. The pots are filled to a little less than two-thirds of their capacity with clean, broken crocks, and these are covered with sphagnum to insure perfect drainage. In potting, care must be taken to set the plant firmly, keeping its base about an inch above the rim of the pot. The plant should be kept moist, although water should be given cautiously until the roots are moving actively in the new material and the growths are developing. When the bulbs begin to form, water must be given freely; in fact, they must never be allowed to get dry until they have developed their flowers.

The greatest enemies to *Miltonias* are yellow thrips, which must be exterminated as soon as they appear; sponging with tobacco-water and fumigating constantly will keep them down. The appearance of spider and thrips is a sure sign of too high temperature and dry atmosphere.

Langwater Gardens, North Easton, Mass.

William Robinson.

Plant Notes.

PRUNUS PENDULA.—This fine, early-flowering Cherry was in full bloom here a fortnight ago. The plant comes to us from Japan, and, although introduced many years ago, as yet it is comparatively rare in gardens. It is a tree of pendulous habit and covered, before the opening of the leaves, with pink flowers, profusely borne on the old wood and on that of the previous season's growth. The great abundance, the charming color of the flowers and the graceful habits of growth give it a very distinguished appearance among our early-blooming plants. It is perfectly hardy and succeeds in any good soil and fairly sheltered situation. The only drawback is that occasionally the

flower-buds are partially destroyed by late frosts. It is propagated by grafting, using *Prunus Mahaleb* or *P. Myrobalana* for stock. There is some confusion in names among the nurserymen in regard to this plant; sometimes it appears among shrubs, sometimes among the trees; at times it is a *Cerasus*, at others it is a *Prunus*; generally the species is given as *Rosea pendula*, but *Japonica* or *Sinensis pendula* is also used. *P. Miqueliania* is also in bloom now, and for garden use it resembles *P. pendula* in everything apparently, except the color of the flowers. They are almost white. Both these trees have been figured in *GARDEN AND FOREST*, vol. i., pp. 198, 199. An illustration of

inscrutable disease which has been called "Japanese-chick-back." It should be given a sheltered position, and the planter must wait patiently for his reward. The flowers are lively rose-pink, which is deeper on the outer portions of the petals, shading to the centre, and their effect is much heightened by the presence of stamens and pistils, which impart a lightness and airiness to the flower wholly lacking in the double form. The propagation is by grafting with *P. Myrobalana* as the stock. The plant is not, probably, in the hands of every nurseryman as yet, but it would not be difficult to work up a stock.

MAGNOLIA STELLATA.—This is the earliest of the Magnolias

Fig. 30.—*Miltonia vexillaria*, "Fairy Queen," in Langwater Gardens, North Easton, Massachusetts.—See page 194.

an old and large specimen of *P. pendula* was also published in vol. ii., p. 487.

PRUNUS TRILoba.—Another beautiful plant now in flower is the comparatively rare single form of the well-known *Prunus triloba flore plena*. This plant has been grown in the Arnold Arboretum for some time, and this year it has bloomed much more abundantly than it usually does. It is a shrub of moderate height and branching habit, resembling the double kind in foliage and growth, and requiring nearly the same general treatment. It seems, however, a trifle more tender, and perhaps a little more subject to that

to flower, and it has conspicuous merit. The flowers are white and borne in great abundance. It comes into bloom a week earlier than the Yulan Magnolias, and, with the exception of *M. Kobus*, is the hardiest of that division of the genus which flowers before the leaves expand. Although it begins to bloom when young in years and small in stature, it, nevertheless, attains good size. A plant in a garden on Jersey City Heights is more than twelve feet high and of equal diameter, and produces annually thousands of blossoms. In congenial soil the growth is good, but by no means as rapid as that of other

members of the family. Time is needed to produce a large plant, but, as nothing is lost by winter-killing, the grand result is, upon the whole, favorable when compared with that of *M. conspicua*, *M. Lennei* or *M. Soulangiana*. The plant needs a deep, rich soil, and, after it is well established, should have plenty of manure. Protect at first with a mulch of leaves in winter, and with evergreen boughs. The mulching of leaves should always be given, as it sometimes serves to retard the time of blooming, which is very desirable in our uncertain northern climate. It is a good plan to water well during the hot July and August weather—not a little sprinkling every day, but water by bucketsful once or twice a week. The propagation is by layers and by grafts, the last method producing the best plants. *M. stellata* was one of the plants sent to the Parsons' Nurseries twenty-five years ago by Dr. Hall, after whom it is sometimes called *M. Halleana*.

TULIPA SYLVESTRIS.—This is the common Wild Tulip and is sometimes called by bulb-dealers *Tulipa fragrans* and *T. Florentina odorata*. It is one of the most beautiful and graceful of all the Tulip species, and deserves a place in every garden where herbaceous plants are cherished. It is now in bloom, coming a little later than the so-called early Tulips, a week or more later than the *Duc van Tholls*. It is a native of Europe, and has been long in cultivation. The flowers are large and bright yellow; they are fragrant, this quality being sufficiently well marked to have given the plant the synonyms quoted above. The great beauty of the plant is the graceful form of the perianth and the pleasing way in which the flowers are borne on the stalks without any trace of the stiffness which so often mars garden Tulips. The segments of the perianth are long and narrow, and the flower buds upon its stem; occasionally two flowers are produced upon the same peduncle. No difficulty attends its cultivation; a deep mellow loam, well drained, and plenty of well-rotted manure are the only requirements. In fact, it grows so easily that it sometimes establishes itself in gardens as a veritable Wild Tulip, the only care required under these circumstances being not to disturb the bulbs. Omit the annual lifting and curing, and let them grow on with the Crocus and Daffodils, disturbing them only when they become crowded. The bulbs are inexpensive and easily obtainable.

TRITELEIA UNIFLORA.—The "Spring Star Flower" is still in bloom, although it begins to flower with the early hardy bulbs. In ordinary seasons it flowers in this latitude in March, and it is quite a showy plant when grown in moderately large clumps. The star-like flowers are for the most part white, with a faint marking round the segments and throat of pale lilac, or they are a delicate lilac as they open and quickly fade to white on the upper surface. The leaves are about six inches long and quite narrow. This species is a native of Buenos Ayres, and there is a large-flowered variety of it called *Conspicua*, which is even prettier than the type. To have the plants in flower as early as possible they should be given, of course, a sunny and well-drained situation. This *Triteleia* makes a fine pot plant in late winter for a cool house, if about a dozen bulbs are set in a six-inch pot in September and kept in a cold frame until about a fortnight before they are wanted to flower.

PAPAVER ALPINUM.—Among all the beautiful plants and flowers of the season there are none more dainty and attractive in leaf and flower than the Alpine Poppies. The neat little mound of finely cut glabrous foliage is alone beautiful, but when above this many flowers of dainty tissue spring in air on slender stems the picture is one great charm. The usual colors of Alpine Poppies are yellow, white and light pinks. These are also often in combinations, as, for instance, a yellow edging on a white ground. *P. nudicaule*, which is botanically almost identical with *P. Alpinum*, has leaves less finely cut, and among these may be found beautiful orange-scarlet flowers, and it seems to be most frequently grown in gardens. The cultivation of Alpine Poppies is very simple. The seed may be sown

either in seed-beds or in the borders, preferably early in the year. The young plants require some care in transplanting, but can be successfully moved at any time. Early-sown seeds will make flowering plants the same season, but will be at their best the second year. While true perennials, these plants are apt to go off from excessive flowering and dampness. Their requirements are perfectly drained places where no water will lodge at their base and a top-dressing over their roots in early spring, as the frosts sometimes are apt to lift them in the early year.

IRIS RUBRO-MARGINATA.—The flowering season of the rhizomatous Irises commences here in April with the flowering of this little Central Asia Minor Iris. *I. rubro-marginata* is allied to *I. pumila*, which is very familiar in gardens as a dwarf border-plant, usually flowering in May. The leaves of this species are falcate, two to four inches high, margined usually with red. The rhizomes are short and short-creeping. The flowers are small, of beautiful compact form, with large standards and of a peculiar vinous color, with metallic reflections. They are borne in profusion, and the plants at flowering-time are quietly, rather than strikingly, handsome.

Cultural Department.

Chrysanthemums for Specimen Plants.

CHRYSANTHEMUM-PLANTS intended for exhibition should now be well established in six or seven inch pots. If they have been judiciously stopped they will be compact, well-balanced plants. It is important we have a good foundation to begin with. Even at this stage the practiced eye can pick out those best suited for specimens. A poor plant now will make a poor specimen. We should not, however, judge by size only. As a rule, varieties inclined to be tall and rather coarse, even though they may be the largest plants now, do not make the best specimens. In the exhibition height is discounted. There are also many novelties received late in the season, which have all the qualities required to make good plants, although they may now be a stage behind. *Portia*, *Lora*, *White Louis Boehmer* and *Minerva*, novelties of last year, were among the largest and handsomest of specimens at the exhibitions. Among novelties of this year which look promising and worth a trial are *Burt Eddy*, *Nellie Elverson*, *Esther Heacock*, *Mrs. Henry Robinson*, *Miss Gladys Spaulding*, *Miss Maggie Blenkiron*, *Vice-President Calvat*, *Nemesis*, *Radiance*, *Nyanza* and *Monsieur R. Dean*.

When we look over our plants we shall find that some of the choicest ones have gone prematurely to bloom. This is unsatisfactory. These rarely make good specimens. It is as if they had to start over again. Often, however, they will break out anew, as did *Cullingfordii*, *G. W. Childs*, *Ivory* and *Louis Boehmer* one season. At this time these were essential in my collection for color-effect, and, having no choice, I had to persevere with them. Whenever I can afford it I always discard such plants, and when I know of this tendency I always fortify myself with duplicates enough for choice.

For large specimens intended for exhibition we use twelve-inch pots. These are really too large; but as the horticultural societies allow this size, it is not likely that exhibitors will run the risk of losing a premium by stint of pot-room. A specimen plant six feet in diameter, and from eight to nine feet over, is far too unwieldy, and the labor of tying out two dozen of such plants can only be comprehended by those who have tried it.

Our soil is light and moderately rich. We use about one-fifth well-decomposed manure; some of us have profited by the mistake of using more. We prefer to feed the plants later, and stimulants can be applied as needed, much depending upon the condition of the plants with regard to health. Lime in some form should be an ingredient of the soil. Bone-meal, if composted a month, at least, before being used, is probably the best fertilizer. It should not be put in freshly. Lime rubbish, or even coal-ashes, will answer quite well for present purposes. The drainage must be thorough. We pot lightly to avoid the risk of overwatering—a misfortune that befalls some of the most promising plants in their earlier stages. Two inches or more is left for water, and an additional dressing of good soil later.

After being potted, our plants are returned to frames for a week or two, and the sashes are kept on—although abundance of air is given—more as a precaution against heavy rain than anything. When nicely rooted in the new soil the plants are

gradually hardened, and finally placed out-of-doors about the end of May. In the mean time, we continue stopping the shoots. We go over them every day, watchful to take the tips out of any shoots which are making unusual headway. It is important that we keep them closely headed in. Soft shoots break much better than those which have been allowed to make from five to six inches of growth before being topped.

We always find room for two or three dozen small specimens which we grow in six-inch pots from May-struck cuttings, stopping them only once or twice, allowing from ten to twelve blooms to each. Compact-growing varieties, needing few stakes, are best suited for this purpose.

Our stock plants for specimen blooms, cut over in March, have now a good crop of cuttings which should be taken at once for exhibition blooms. For general decorative purpose nearly a month later will be early enough.

The cuttings should be inserted as quickly as possible after being taken, as if wilted to any extent they take a longer time to root, as well as suffer a constitutional loss. Abundance of water will be required for the first few days, and the plants should be shaded when the sun shines. As the rooting goes on, less and less water and shading will be needed, and at the end of three weeks all should be rooted and hardened enough to be potted off or boxed, according to the convenience of the grower.

Wellesley, Mass.

T. D. Hatfield.

Flower Garden Notes.

MOST of the ornamental-leaved and flowering plants for bedding out can be planted out from the middle to the end of the present month. In this latitude Geraniums can be set out with perfect safety by May 15th, but we prefer to wait until the 20th, so that all the plants may be sufficiently hardened off and that the planting may be done as quickly as possible. Geraniums, Ageratums, Tuberous Begonias and other moderately hardy plants are now in cold frames; the sashes are thrown off, except during cold nights. Begonias dislike direct sunshine, and we run a lath shading over them during the middle of the day. Coleus, Alternanthera, Cannas and other more delicate plants are now in a cool house and will be placed in frames about the middle of the month. From this time copious supplies of water will be needed by all plants in pots or boxes, and special care should always be taken at planting out time to have the balls of earth thoroughly wet. Neglect in this particular is the cause of many plants doing so unsatisfactorily. If a plant is thoroughly pot-bound and dry at the root in addition when set out, no ordinary waterings or rains will penetrate the ball of earth, and a small hollow space should be left around each plant to catch the water.

Among flowering plants Geraniums still hold a leading place, and will, no doubt, always do so. They become rather straggly by August, and heavy showers of rain give them a disheveled appearance. To restrict the growth somewhat, it is the custom with certain growers to plunge the plants out in the pots. This is done in the Public Gardens in Boston, and may be a good plan where a good water-supply is at hand. If plants have no special care, however, after being placed in the beds, this plan would not be successful. I have never been specially struck by the beauty of the Geranium beds in the Boston Public Gardens, and if they are a fair sample of what may be expected from pot-plunged plants, I prefer to stick to the old system. Cannas now occupy a front rank as flowering plants, and deservedly so; for large circular beds and wide borders they are unexcelled. Tuberous Begonias, where heavy or even partial shade can be obtained, are worthy of more extensive cultivation. We have tried them in full sunshine, but even when well watered and mulched they grew unsatisfactorily and burned badly. Begonias love a rich compost and abundant waterings during dry weather. Treated thus they are superior to Zonal Pelargoniums in every way, and the ease with which they are raised and can be kept over winter should commend them to all flower-lovers.

There are many plants now looking a little leggy and ungainly in the greenhouses which can be put to good uses in mixed borders. Among these are Abutilons in variety, Hibiscus, Datura suaveolens and D. cornucopia, Plumbagos and others. Begonias of the fibrous-rooted section will all do well on a partially shaded border, and a mixed assortment of these was as attractive as anything we had last summer. Those of the Rex section are good in rockeries or in any other situation which is rather heavily shaded. Crotons, Pandanus, Caladiums, Dieffenbachias, etc., cannot be exposed here before the middle of June, and the season for them is so short that very few care to go to the trouble of placing them outdoors. Aca-

lyphas, however, prove excellent bedders, and are being used in increasing numbers.

Our early sowings of Stocks and Asters are usually planted out about May 10th; of the first-named, Boston Florist, and of the latter, Queen of the Market, are the earliest. We continue to sow these at intervals of a fortnight until the middle of June for successive crops. Marguerite Carnations, Dianthus, Gaillardias, Verbenas, etc., are planted about the same time as Stocks and Asters. Zinnias, Phlox Drummondii, Cockscombs, Torenia, Salvias and others are left ten days later. A good number of these are dotted in perennial borders to brighten them up from the end of July onward, when otherwise these borders would present a decidedly unattractive appearance. Seedlings of perennials should now be planted out in nursery-rows and transferred to permanent quarters in the fall. Perennial borders will require hoeing and raking to keep them neat; few plants will yet require staking.

The past winter proved a destructive one here; Helianthus in variety were killed outright in some situations, something which has not happened for years before. This damage is due to the light protection of snow we had all winter long. On the other hand, Tritonias, Pyrethrums, double and single, and Anemone Japonica have come through unscathed, and, although usually these are considered tender, they withstood a temperature of ten degrees below zero, with no snow or other covering to protect them. Roses are now breaking nicely. We give these a mulching of good cow-manure all over the beds during this month. This keeps the roots cooler and retains moisture, very essential things in the cultivation of hardy Roses in America.

Grass verges have all been gone over with the edging-iron recently, and the verges will require clipping weekly from this time onward. Nothing so much adds to the appearance of a place as good lawns and well-kept verges, yet even in some of our leading parks the edges of the flower-beds do not seem to have had an edging-iron or pair of shears over them during the whole season; no matter how well a bed may be planted, if its verges are slovenly kept it is something of an eyesore to those who have been properly trained in their profession.

Taunton, Mass.

W. N. Craig.

Early-flowering Hardy Perennials.

THERE are few hardy herbaceous plants in early spring that give as much pleasure and produce such showy flowers as a good strong, healthy specimen of Adonis vernalis. The ground is hardly free from frost when it begins to push up its stems, and very soon the stems are crowned with large, yellow, anemone-like flowers. I have had several complaints about this plant from people who say they find it rather difficult to grow and flower successfully. It does admirably here, and the treatment given to it is very simple. It is grown in a border where it gets the full benefit of the sun all day. Care is taken, when planting, that it is not put beside any large plants that will shade it or rob it of its nourishment. Every third year the plants are taken up carefully and the border is double dug and enriched with manure. It is not beneficial to disturb the plant oftener than this. Small plants are not as satisfactory as large ones. The small plants only bloom for a short time in April; but large, strong plants bloom well into May. Hence the reason for not dividing them too much. Although this plant comes from southern Europe, it is one of our hardest of perennials. It never needs protection of any kind in our very severest winters.

The Hepaticas are among our earliest flowers, and most of them are over now. Under the shade of a Hemlock-tree, a few flowers still linger on Hepatica angulosa, the best of all of them. It is a beautiful plant, and its lovely sky-blue flowers are much larger and showier than those of H. triloba or H. acutiloba. It is quite hardy and delights in a rather shady position with deep, rich, moist soil.

Primula denticulata makes a good rock garden, and a large mass of plants are flowering well at this time. The flowers are produced in dense round heads on stems six to eight inches high; they are of a deep lilac color. The plant comes from India, but is quite hardy here. It thrives in moderately moist soil, and the flowers last longer if they are slightly shaded.

The large-leaved section of the genus Saxifraga is quite conspicuous in the herbaceous border now. In early spring, in exposed positions, the large evergreen leaves are rather unsightly after our severe winters; but the young leaves soon expand, and are almost full grown, if planted in a warm position, before the plants are in full bloom. S. cordifolia has

large heart-shaped leaves six to ten inches across. Its rose-colored flowers are produced in large panicles on stout stems nearly a foot long. *S. crassifolia* is also in bloom, and is closely allied to the above. It has large, leathery, oblong leaves. The flowers are of a reddish color, and are also produced in large panicles on thick stalks eight to ten inches high. Both of the above plants come from Siberia and are very hardy. They are desirable for the rock garden, and if they have partial shade their large bold leaves are not so much destroyed in winter. The soil they thrive best in is a light rich one, where they make large healthy leaves, which are attractive when the plants are not in bloom.

The White Rock Cress, *Arabis albida*, is at its best now. We use it in the front row of the herbaceous border, where its racemes of white fragrant flowers are seen to the best advantage.

Phlox subulata, the Moss-pink of old-fashioned gardens, is so full of bloom at this time that its leaves can hardly be seen. It is an exceptionally good plant for a dry sunny border, and seems to grow the best in the dry summer weather.

Cambridge, Mass.

R. Cameron.

Begonias for Bedding Purposes.

A PART from the tuberous-rooted Begonias there are several species and varieties which, on account of their handsome flowers and foliage are very suitable for the outdoor garden during the warm months. *B. Evansiana*, from eastern Asia, is quite hardy in Washington, having stood out in the Botanic Garden for the past thirty years. The roots, of course, die out, but the little bulbils which form around the axils of the leaves come up thickly in the spring and form nice blooming plants in a few weeks. *B. Evansiana* is valuable both for its leaves and flowers. The best of those valued for their flowers alone is the old *B. coccinea*; it stands the sun well; in fact, the more sun it gets the better it likes it. The flowers are produced in large pendulous clusters, and, as the specific name denotes, they are red; the female flowers are the showiest, lasting a long time in perfection. This species revels in very rich soil; large plants in small tubs when in flower—and you scarcely ever see them without flowers—are very desirable to place on lawns around a dwelling. The best manure is that from the poultry-yard. Mix it up with equal parts of loam and leaf-soil several weeks in advance of the time when it will be required for use, spread it out and let the sun dry it thoroughly; this makes the plants put on a strong growth, producing a wealth of bloom that is remarkable.

The hybrid called President Carnot is a stronger grower, standing the sun equally well; it makes larger trusses of flowers than *Begonia coccinea*, but not so many of them, and it is more serviceable as a winter bloomer. *B. caroliniae-folia*, a species forming a thick succulent stem, is good for its old palmate leaves. *B. Weltoniensis* and *B. Dregei* are free bloomers when planted in partial shade; they need open soil and must be kept watered. *B. Vernon* sometimes does admirably, but it is an erratic grower here. This variety comes true from seed, the seedlings blooming when only a few weeks old.

Begonia Erfordiae is by far the best of the recent introductions for bedding, and it has proved itself a first-rate acquisition during the two seasons I have tried it; there are two colors among plants of it raised from seed, a clear pink and a creamy white; the pink is the most valuable, as there are other whites superior to this. *B. Erfordiae* may be said to flower itself to death, as cuttings of the flowering wood are next to useless; they continue flowering without making side-shoots. It seeds freely, however, and should be included among the plants for spring sales by those who grow bedding-plants. *B. Wettsteinii* has *coccinea* blood in it, although it is a more fragile grower. *B. Diadema*, in a slightly shaded place, makes a nice display with its white spotted leaves, and *B. alba-picta* is good for the same purpose. Among the creeping varieties, *B. scandens* does well when grown in good soil and kept watered; the flowers of this species are snow-white, very small, but they appear in great numbers.

Botanic Garden, Washington.

G. W. Oliver.

Bedding Out.—Where much summer bedding is done the planting-out season is always a busy time, and much time is saved by having the designs and planting plans all ready beforehand. The principal points to be observed are the tasteful blending of colors and the most agreeable contrasts. The selection of plants will be largely determined by the location and size of the beds and borders. If the borders and beds, for example, have a background, or if they are situated so that the plants are intended to form a screen to break an undesirable view, the plants for the back row should be tall. The best effect would then undoubtedly be obtained by planting in lines

lowering gradually toward the front. If the borders are near the margin of a lawn where the view should not be obstructed, a better effect is obtained by having a groundwork of one kind of plants with other sorts planted through it in masses. Plants of the medium dwarf sorts may be used instead of regular carpet-bedding kinds, which are apt to look too squat in a border.

Beds must also be filled with plants corresponding to their size and position. Those at a distance in prominent positions require something large and showy, and for this purpose Cannas are most admirably adapted. A mass of the scarlet Madame Crozy, with a border of Caladium esculentum gives a good effect, while for those nearer the walks low-growing plants should be chosen. It sometimes happens that beds are placed in a shady position, in which case soft-wooded or flowering plants would be far from satisfactory, but such plants as Yuccas and Agaves should be used, the tallest plants being placed in the centre, and the others graduating to the edge, finished with a border of low-growing Echeverias.

Tarrytown, N. Y.

William Scott.

Nymphaea Laydekeri rosea.—This is one of the best of the small-flowering Water-lilies for general use either as an ornamental plant or for cut flowers. While it grows as freely as any of the other kinds, it has baffled all attempts at propagation, so far as known. The plant keeps on growing from the same crown, forming a thick succulent stem, the lower part of which is continually decaying as the top makes new growths. I have tried to increase it in various ways, but never have succeeded in even starting a lateral growth, and the worst of it is, the plant usually dies if it is disturbed too much. I have killed four plants already, and am as far from a solution of the problem as ever. Several other people have tried to propagate it, with like results. It sometimes produces seeds, but they do not come true. I am inclined to believe that the best way to raise it is to cross-fertilize the two parents every time seed is wanted, and thereby renew it in the same manner in which it was originally produced. Its parents are said to be the Chinese *Nymphaea pygmæa*, fertilized with pollen from the pink variety of *N. alba*. I am the more inclined to believe these to be its parents, because, for want of the flowers of the last-named kind, I have tried pollen of a dark form of *N. odorata* rosea on flowers of *N. pygmæa* with successful results. The flowers of this hybrid are nearly of the same color as those of *N. Laydekeri* rosea; there are more petals to the flower and the shape is more star-like.

Botanic Garden, Washington.

Correspondence.

Notes from a West Virginia Garden.

To the Editor of GARDEN AND FOREST:

Sir,—Among many shrubs now in bloom at Rose Brake, *Xanthoceros sorbifolia* (see GARDEN AND FOREST, vol. vi., p. 285) is the most beautiful. It is now a compact bush, five feet in height and is covered with its delicate blossoms, as large as those of the Weigelia. They are pure white, with centres of a pale greenish lemon color when they first open, and gradually deepening to a peculiar shade of deep red. The *Xanthoceros* remains in bloom a week or ten days, according to the weather, and is a very showy and striking acquisition to our list of hardy shrubs. The foliage is well developed at present only on the lower limbs. It resembles that of the Mountain Ash, as its specific name indicates, but is darker and more glossy. The habit of the shrub is graceful and compact, so that it is attractive at all seasons and should have a place of honor in the garden. I wish some one would give it a prettier name.

The wild garden and the rockery are now most interesting. Two varieties of *Senecio* are flowering, both native to our woods. These are the interesting *S. aureus* (Squaw-weed), with its beautiful purple-lined leaves and heads of showy yellow composite flowers and its taller variety, *obovatus*. *Phlox subulata* is still flowering, and *P. divaricata* is very pretty now in the woods, but, though easy to transplant, it does not flourish in the heavy clay soil of our garden. It is not an aggressive plant and is easily discouraged by the encroachments of grass or perennials of strong growth. It seems to require the rich loam, partial shade and leaf-mulching of open woodlands for its best development. It is such a charming plant that it is a pity we cannot give it the conditions it requires. It seems to me the most refined and pleasing of all the Phloxes. (*P. divaricata* was figured in GARDEN AND FOREST, vol. vii., p. 256.—ED.)

Veronica Buxbaumi is a bright-eyed, cheerful little plant,

which has wandered here from Europe and is desirable for the rockery because of its hardness, its very early and profuse bloom, and the extraordinary duration of its time of flowering. How it came here is a mystery, but it suddenly appeared one spring in a neglected border and has held its own ever since. It begins to bloom in March and thrives on scanty soil. *Saponaria ocymoides* is a showy little trailer, also from Europe, just beginning to open its small pink flowers. It is useful and pretty when planted in a crevice of the rocks, which it curtains with its delicate bloom. It is one of the little plants to which we become greatly attached. Its near neighbor, *S. Japonica*, does not bloom until July.

Mertensia Virginica is now beginning to fade. This is an admirable plant for massing. One can hardly have too much of it in the wild garden, where its sheets of sky-blue are very effective at a time when so few herbaceous perennials are yet in bloom. We have planted large clumps of it at the foot of the rocks, and here the wild Columbine nods to it from the cracks and crannies above, contrasting its red and yellow blossoms with the dainty azure of the *Mertensia*, and forming a beautiful picture such as may often be seen in our native woods.

To-day, May the seventh, I plucked the first Rose from a bush of *Rosa cinnamomea*, the Rose Tangle, among the rocks.

Danske Dandridge.

Shepherdstown, W. Va.

The Exhibition of the National Sculpture Society.

To the Editor of GARDEN AND FOREST:

Sir,—The exhibition of works of sculpture in connection with gardening art, now open in the Fine Arts Building, on Fifty-seventh Street, is much more genuinely successful than could have been expected. For one thing, less has been attempted than we were led to believe would be the case by the anticipatory circular issued some weeks ago and then commented upon in the editorial columns of GARDEN AND FOREST. No effort has been made to show, or even to suggest, schemes of landscape-gardening, or even of naturalistic gardening on a small scale; and, of course, these were the schemes least well adapted for treatment in a restricted and covered space, with such plants as could be supplied in pots, and without the possibility of using expanses of grass. And, in the second place, in treating the formal gardening ideas which alone have been attempted, architectural elements of a more important and effective sort have been achieved than one might have thought would be attempted for so transitory a purpose.

As deputies of the National Sculpture Society, the first care of the projectors was for their own art. They wanted to show, not the possibilities and the attractions of formal gardening as such, but the essential service it can render as a setting for works of sculpture and the architectural elements which are their natural, and often their indispensable, accompaniments. They wanted to convince the public that all kinds of statuary suitable for outdoor use might be more artistically and effectively used than any of them are to-day in this country, and especially that, with proper surroundings, works of an ideal character come into this category to a much greater degree than we now realize.

From this point of view, the fact that they had to make their exhibition indoors was not as great a drawback as may be thought. A circular which they have recently issued says that this exhibition ought to suggest to the public "the possibility of creating a purely American conservatory garden which will be a real home for sculpture a garden which could be kept covered with glass during five months of winter by means of sections of glass frames, thus forming a conservatory, and which would be uncovered during the other months of the year, thus forming an open-air garden. Hitherto it has been argued that the severity of our climate made the placing in gardens and parks of marble statues a useless waste of money; but this argument will no longer hold good." And, indeed, the present exhibition shows what a delightful place might be created in this manner, while it suggests possibilities of more extensive treatment on a larger scale out-of-doors, when works in bronze, capable of resisting the effects of our winter weather, might be employed, or roofed alcoves and colonnades might protect more perishable materials.

In the first gallery, which runs all across the breadth of the Fine Arts Building, a series of clipped hedges, well disposed in variously curving lines, cut off the corners of the rooms, and supply niches and alcoves where statues are effectively set. The steps which, opposite the entrance door, lead up from this room into the small central apartment, are now masked by a temporary balcony, with a handsome balustrade

and flights of steps leading up to it from either side; and in front of this balcony is a large flower-bed, of complex but symmetrical outline, which offers an excellent suggestion in regard to the way that the effect of the porches and piazzas of our country-houses might be improved by some semi-formal transition between them and the lawn.

Standing on the balcony and looking through the central room (where no gardenesque work has been attempted) we get a beautiful view into the big Vanderbilt Gallery, which has been utterly transformed from its usual aspect. This great square room is now divided into three unequal parts (the largest being the middle portion) by high walls, seemingly of marble, which run from the entrance nearly to the opposite wall of the room, where they are connected by a tall Ionic colonnade. The walls are some eight feet in height, with several massive piers which rise higher and are surmounted by ornamental plants (chiefly Palms) in huge pots and vases. On each side the wall retreats into a circular niche, filled by a fountain of running water, over which presides a statue of a child, appropriate in character to its place; and in front of each wall, likewise leading the eye toward the colonnade, runs a row of Tree-ferns, fifteen feet high, growing, of course, in tubs. Through the colonnade, the entablature of which is formed by a beautiful bas-relief by Mr. Herbert Adams, destined to adorn the Baptist Church on Washington Square, we see a lofty hedge of green, and against this stand three white statues, each opposite to one of the intercolumniations, and being thus effectively enframed to the eye; and these statues have been carefully selected for their simple dignity of outline—for a sort of semi-architectonic character thoroughly appropriate to the use to which they are put as complements of the architectural scheme.

All the architectural elements are constructed of white plaster, in the same way, I suppose, that the work of building the Chicago Fair was done; but they look solid and marble-like, and they are so handsome in themselves, alike in their proportions and their simple details, and so well adapted in scale to the room in which they stand, that I found that people who had not previously seen the room supposed, of course, that they were permanent features. The success achieved in this direction seems all the more remarkable when we remember that the organizers of the exhibition had possession of the galleries for less than a week before the opening day. The work was directed, I understand, and the designs made, by Mr. Thomas Hastings, of the architectural firm of Carrère & Hastings, assisted, of course, by the counsels, the taste and the practical help of many other members of the Sculpture Society.

Messrs. Pitcher & Manda have lavishly aided these gentlemen by supplying them with the plants needed for the carrying out of their scheme. Of course, its horticultural elements must not be too strictly judged for the quality of appropriateness, either as regards the special service to which some of them are put or their effect as a whole. Under such conditions, not the best possible, but only the best available, plants could be utilized, and this must be borne in mind when estimating the result. The many hedges, some of which are very tall, are not growing, but manufactured, hedges, composed of branches of the Red Cedar, *Juniperus Virginiana*. But these have been so skilfully set and supported and bound together that the deception is not apparent even when they stand in such a way that both of their sides are visible. The Tree-ferns, which form, as it were, a natural colonnade, leading the eye up to the marble one, are beautiful specimens, nearly alike in height; and many of the Palms and similar plants which fill the great pots and vases on the piers of the wall and of the balcony balustrade in the first room deserve equal praise, while the pots and vases themselves are often very beautiful. Among them one fancies that he recognizes individuals that figured upon the New York Building at the Chicago Fair, which, it will be remembered, was decorated with such plant receptacles, specially imported by Mr. McKim, from Sicily, if I am not mistaken.

The beds of hardy herbaceous plants contain interesting specimens in flower, and, although they are grouped as harmoniously as is possible under the conditions, few of them can be considered appropriate settings for the works of art they support. Some small deciduous trees, just coming into leaf, add a touch of refinement to the general effect, although they do not accord very well in character with their tropical neighbors. Some collections of Orchids, massed on shelves in the corners of the rooms behind the hedges, are even less well suited to their places, although they are well worth examination on their own account. Other specimens of Orchids have been suspended from the trunks of the trees, and Stag-horn Ferns and Pitcher-plants have been attractively

used in the adornment of the fountain-niches. The large bed which lies in front of the balcony in the first room is edged with Box, but filled with tropical plants too high for their positions. It should never be forgotten that such beds as these, however beautiful their design may look on paper, are never effective in actuality unless one can recognize the patterns they make at a glance; and this, of course, is impossible, except from an elevated position, unless they are filled with very low-growing plants.

This is not the place in which to speak in detail of the works of sculpture which were the *raison d'être* for the exhibition. I can only say that there are many very good ones among them, and that, as a whole, they will probably give the public a truer idea of the development of this art in America than it has hitherto conceived. Moreover, it is now enabled to form some judgment with regard to the kinds of work which are best fitted for outdoor display, while even our sculptors themselves ought to learn much in regard to the necessity for placing their outdoor figures with care. The beautiful effect of white stone against green backgrounds is not the only point made plain. We realize that a work of a scale too small to look well if stationed quite "in the open" may look admirably out-of-doors if it forms an adjunct to some architectural motive or is set in some verdant corner where it will not be palpably out of scale with its environment. And also that, when a statue or group is not equally beautiful on all its sides, it is as possible as desirable, out-of-doors no less than indoors, so to place it that only those sides which are most satisfactory shall be visible.

On the whole the executives of the Sculpture Society deserve high praise for the originality, the energy and the good taste they have shown in organizing and arranging this exhibition. So pretty and attractive is the general effect of these galleries just now that even persons possessed of no distinct artistic or horticultural tastes ought to find much delight in visiting them.

M. G. Van Rensselaer.

New York.

Notes.

A writer in *The Strawberry Culturist* has been testing different varieties of strawberries for fruiting under glass, and he finds that the comparatively new Brandywine yields the greatest amount of good fruit.

A grower of strawberries in Maine finds boughs or small trees of Spruce or Pine the best material for covering the plants in winter. These collect and hold the snow, which is the best non-conductor of heat, while permitting, at the same time, a sufficient circulation of air.

European orders are arriving in California for considerable quantities of redwood, to be used in the making of lead-pencils. This timber varies a good deal in the quality of its grain, but the best of it is found to be an acceptable substitute for Florida cedar, which is becoming rare.

Texas did not escape the cold weather which visited other southern states, and snow two feet deep fell along the coast in February. The season was, therefore, unusually late, and such plants as Dog-tooth Violets and Bluets, which usually flower in February, did not appear until the middle of March.

Daphne Cneorum, always an uncertain little evergreen here, seems to have come through the winter unusually well, and is now covered with its fragrant pink blossoms, and there is nothing better than this trailing shrub for rock-work. Flowering at the same time, but a good deal more hardy and trustworthy, are the half-shrubby perennial Candytufts. The flowers of these Candytufts are as white as snow, and since the plants resemble the Daphne in habit the two make admirable companions.

Mr. J. H. Hale writes to the *Florists' Exchange* that, although the Fay Currant has been introduced more than ten years, and has been propagated ever since by all the nurserymen of the country, it still commands a higher price than the older varieties of Currants. It seems strange that when this is known to be the case that the stock of the country is invariably sold out every year before the end of the season's trade. Perhaps one reason for this is that this variety does not root readily from cuttings, and that when it does root it never makes as strong a growth as the Victoria, the Cherry or the White Grape, so that from an equally-sized block of plants at least one-third more salable bushes of other varieties can be dug than of the Fay. Of all Currants the North Star is the easiest to grow and propagate, and under ordinary conditions it has grown to a height of four feet from cuttings in a single season.

Writing to the *American Agriculturist*, Mr. John N. May advises any one who can afford to buy only one Rose-plant to select Clothilde Soupert. This Rose belongs to the Polyantha class; it is perfectly hardy and blooms until frost; the flowers are a beautiful soft pink when they first open, changing to a pearly white as they get older; they are of excellent form and sweet-scented. After Clothilde Soupert, Mr. May recommends Mrs. Degraw, a Rose of the Bourbon class, glossy pink, and continuously in bloom; Souvenir de la Malmaison, another Bourbon, large, flesh-colored; La France, a Hybrid Tea, clear soft pink; General Jacqueminot, a Hybrid Perpetual, crimson; Duchess of Albany, another Hybrid Tea, a sport from La France, deep pink in color; and Dinsmore, a Hybrid Perpetual, coral-red. To these can be added Empress Augusta Victoria, white; Papa Gontier, bright red; Etoile de Lyon, yellow—Tea Roses which are not quite hardy, but which can exist through ordinary winters with good protection.

The very warm weather of the past two weeks has hurried forward large supplies of southern vegetables, the crops that were planted in Florida after the February freeze having become marketable at the same time with vegetables from North Carolina and Virginia. Asparagus, for example, on Friday of last week sold at wholesale for as little as thirty to seventy-five cents for a dozen large bunches. Hundreds of crates of beans and peas from Florida were left unclaimed on the docks by consignees, since they could not be disposed of at prices which covered the expenses for freight, and these perishable vegetables were carted away and destroyed at an additional expense to the steamship companies. French artichokes from New Orleans, much smaller than those which have been coming from Algiers, bring seventy-five cents a dozen. New Brussels sprouts from Bermuda cost twenty-five cents a quart, and celery from the same islands twenty-five cents a bunch. Strawberries are plentiful, and those from Norfolk bring as much as thirty cents a quart retail for the choicest. The Maryland crop is expected to arrive during the current week.

California oranges, both Navel and seedling, are still arriving in large quantities, ten car-loads of this fruit having been sold at auction in this city on Monday. Prices are low, and the cost of shipment is hardly covered. Bananas are bringing extreme prices, the best grade from Aspinwall, Banes and Sama realizing from \$1.75 to \$2.00 a bunch by the truck-load on the docks. About 23,000 barrels of pineapples came into this port from Cuba during last week, and schooners from the Bahama Islands are bringing large quantities in bulk. The shipments from Nassau will continue until about the middle of July, or a month later than those from Havana. Much of the Bahama fruit was canned at home last season, but the experiment seems to have been unsatisfactory. The decay in pineapples is a very considerable item in determining prices for the sound fruit. The first pineapples of the season are naturally rather green, and they carry better because they are more firm than riper fruit. The percentage of decay in the green fruit amounts generally to ten or fifteen per cent, though the average decay in the riper Havana fruit reaches thirty-five or forty per cent., and the loss sometimes amounts to as much as ninety per cent. The weather is largely responsible for decay, especially in the loose cargo lots, the moisture from rains in the green tops occasioning fermentation.

According to Dr. T. H. Hoskins, the Apple known as Scott's Winter is practically the only valuable native variety which will thrive in his climate on Lake Memphramagog and in the Clyde River valley and yield fruit that will keep all winter. This fruit is not at its best until about the first of April, and it will keep well a good month longer. All through the north-west, as well as in northern Vermont, especially in Wisconsin, Iowa and Minnesota, it is considered the best apple for the late winter market. No other variety so productive of such handsome fruit will grow north of the point where the Baldwin fails to endure the cold. A fence-corner seedling, it was introduced by Dr. Hoskins some twenty years ago and named for the owner of the farm where it originated on the west shore of Lake Memphramagog, less than a mile from the Canada line. The original tree is said to be in good condition still. Dr. Hoskins is propagating another late winter Apple-tree from Russia, which bears what he regards a better dessert fruit than Scott's Winter. A specimen of this apple sent to this office is of fair size, a beautiful color and pleasant aroma. The flesh is firm in texture and fine in grain. The flavor is hardly sprightly enough to suit an educated taste, but for the cold north, where few good kinds will grow, the hardiness of the tree and the admirable keeping qualities of the fruit ought to make it a most desirable variety.

Popular Books about Flowers.

ONE of the noteworthy features of current popular literature is the large number of publications on the subject of our native wild flowers. Most of these books have had a large sale, and the natural inference from this would be that there is a growing interest in botanical science. It is possible, however, that the plan of doing out information in unrelated scraps and bits is not the true way to impart scientific knowledge. The teacher who does no more than fill up the minds of his pupils with fragments of truth really renders him little assistance and may inflict upon him a genuine injury. One who imagines that he is improving his mind when he is simply memorizing facts which others have discovered makes a fatal mistake. The real educational advantage derived from the study of a science is not so much the truth that is acquired as the habits of personal and self-reliant observation which are gained. Most of the books, however, to which we have alluded make no pretense of being scientific. Indeed, it is often announced as one of their conspicuous merits that they are cumbered with no science and with as little scientific language as possible. They set out with the assumption that systematic botany is a forbidding subject, and they aim, therefore, to impart information about plants in an attractive way, and this apparently means in an unsystematic and desultory way which is supposed to make moderate demands on the attention of the reader. What they propose primarily is to enable the reader to find the name of a plant by some method which will not require any effort. Sometimes the lists of flowers are arranged according to their color, or again according to their season of bloom, but they are never grouped or classified according to their structural affinities, which would seem to be the most natural way for people who have eyes and the power of association and comparison.

Two reasons are assigned for preparing treatises of this sort. One is the notion, and a silly one it is, although it has been put forward by men who ought to know better, that scientific knowledge destroys all sentiment and poetic feeling, and that the more one knows of the structure and vital processes of plants the less he is alive to their

beauty. If one should claim that an acquaintance with geological science destroys all appreciation of the grandeur of mountain scenery, and that a knowledge of astronomy renders its possessor blind to the splendors of the starry heavens, the natural reply would be that only those who realize the vast periods of geologic time during which the earth has been molded into its present form, and the illimitable space through which the heavenly bodies are wheeling, as revealed by astronomical science, can receive any adequate impression of the sublimity of the earth and skies. Just so one who studies with microscopic care the structure of a flower, with its adjustments and relationships, feels more of its true poetry than the casual observer, who notes only its exterior graces of form and color. The second reason offered is that the scientific names of plants are repulsive, and that still more so are the names applied to their different organs and the processes of their development. But, as we have explained before, the difficulty in both cases is exaggerated. The botanical names of plants, it is true, are not always what they should be, but most of them mean something, and, as a rule, they are as easy to acquire as the common names, many of which are applied to half a dozen different species, while almost every ordinary plant has, at least, as many common names. It is the universal testimony of all who have made any serious study of botanical science that these plant names are not half as formidable as they seem, and that they invariably help, rather than hinder. Of course, as soon as one examines a plant or anything else carefully, and wishes to distinguish its various parts, some name must be invented, and we must talk of petals and pistils and stamens, and all the rest, as soon as we begin to separate the plant into its component parts. As soon as we learn to distinguish things we must have names to represent them, and it is impossible to write or speak intelligently of plants without using new terms unless we adopt clumsy circumlocutions. It is not objected to the study of elementary arithmetic that a boy must learn the meaning of dividend and subtrahend; it is simply the necessity of supplying a word to represent accurately a new idea.

Now, it is not to be inferred from all this, that we object to what is called the popularization of science. The real danger from these books is that they have a tendency to vitiate the popular idea of what real science is. One who has been helped by the means of pictures and other assistance to apply the proper names to one hundred and fifty different plants has the advantage of just that amount of mental furniture. When he hears one of these names he knows what plant is referred to, and he is certainly better off than one who does not know this much, but, of course, this knowledge gives him no title to the possession of any real botanical science, and the danger is that young people who are helped to such a trivial amount of information will be prevented from an effort to acquire more, and will be deprived of enjoying the fruits of genuine personal application. It is quite as easy for young people to begin right. It is not to be expected or hoped that many of them will make any great progress in the intricacies of this science, but, as far as they go, their knowledge can be accurate and systematic, and they can have the advantage of their training powers of attention and comparison. They may get no farther than the very rudiments of the science, but, as far as they go, it will be true science, and they will have not only the mental improvement, but the sense of power as well as the pleasure which comes from orderly study and the attainment of knowledge by the exercise of their proper faculties. What the student gains by his own investigation is not only useful knowledge, but it helps him to acquire other knowledge. It is not the facts that are so much needed by the student as the development of the habit of systematic observation.

The real work of this kind must all be done by the student, although, of course, this work will be much more effective under the sympathetic guidance of a skilled instructor. Instead of waiting till he can find a flower and

carry it to the book to hunt up its picture he can begin with the first leaf he sees, and note its outlines and appendages and peculiarities of position. One of the great botanists of the age has said that when a child with the plants in his hand learns to discriminate, by his own observation, between such parts as the simple, heart-shaped, opposite stalked leaves of a Lilac, and the compound, alternate, stipulate leaves of a Rose, he is gaining the habit of acquiring knowledge which is not at all measured by the amount or the kind of information received. It is not a matter of much moment whether he learns such trivial facts as those mentioned, but it is of the highest importance that he should be taught how to obtain knowledge by such direct observation and comparison. Of course, his studies should commence with the observations of the simple external forms of plants with the more obvious roots and stems, leaves, tendrils, veins, flowers, etc., but such a beginning forms a habit which will surely carry him forward to more difficult fields.

The word science has a formidable sound to many ears, but it really means nothing but systematic knowledge. Every child during the earlier years of its life is engaged almost continually in what is practically scientific study. He is examining every phenomenon that presents itself to his senses ; he observes things, he compares them, he naturally forms some idea of their alliances and classifies them by their prominent characters. The best thing that a teacher can do is to encourage him in just this sort of work instead of giving him a book to tell him what some one else has found out. Of all the natural sciences botany is the most convenient for training the eye to see and the mind to note relations with alertness. Material for this study is at hand everywhere and at every season. These popular books are all flower-books, but the flower is only a part, and a small part, of the plant. Every tree invites investigation — its general form, the ramification of its branches, its bark, its winter buds, all open wide fields for delightful study as the student's mind improves and he becomes more able to draw conclusions from what he sees. There are lessons in every window-plant in winter, and even in the dried stalk of every wayside weed. Professor Marshall Ward, whom we have already quoted, has well said that a Hyacinth bulb, when compared with a Potato tuber, makes a most interesting object of study, and so does every nut and apple and orange which a child eats.

All this means that science can only be acquired by study, and not by reading popular flower-books. But study, so far from being drudgery, is delightful occupation. Studious habits are easily acquired by the young, and botanical science, when properly prosecuted, is one of the best ways of training the eye and the mind to habits of attention. Besides this, it is a study which brings one into close contact with nature, and stimulates a love for natural objects, which will increase with years and prove a life-long joy and solace.

Parks, Parkways and Pleasure-grounds.—II.

IN our last issue we quoted from the *Engineering Magazine* portions of an article on this subject by Mr. Frederick Law Olmsted, which discuss the government of parks and the points to be considered in choosing their sites and boundaries. The selections which follow include the greater part of what Mr. Olmsted says in relation to the plans or designs of parks and to the construction of parks :

In order to be able to devise a consistent plan, such as may be followed during a long period of years with surety that the result will be both useful and beautiful, it is necessary, in the first place, to define as accurately as possible the ends or purposes to be achieved. As already remarked, these ends or purposes are as numerous as are the various modes of recreation in the open air. Thus, a small tract of harbor-side land at the north end of Boston has been acquired by the Park Commission in order to supply the inhabitants of a poor and crowded quarter with a pleasant resting-place overlooking the

water, and with opportunities for boating and bathing. Accordingly, the plan provides a formal elevated stone terrace, connecting by a bridge spanning an intervening traffic street with a double-decked pleasure-pier, which in turn forms a breakwater enclosing a little port, the shore of which will be a bathing beach. In the adjacent city of Cambridge a rectangular, level and street-bounded open space has been ordered to be arranged to serve as a general meeting-place or promenade, a concert-ground, a boys' playground, and an outdoor nursery. Accordingly, the adopted plan suggests a centrally placed building which will serve as a shelter from showers and as a house of public convenience, in which the boys will find lockers and the babies a room of their own, from which also the head-keeper of the ground shall be able to command the whole scene. South of the house a broad, but shaded, gravel space will provide room for such crowds as may gather when the band plays on a platform attached to the veranda of the building. Beyond this concert-ground is placed the ball-field, which, because of the impossibility of maintaining good turf, will be of fine gravel, firmly compacted. Surrounding the ball-ground and the whole public domain is a broad, formal and shaded mall. At one end of the central building is found room for a shrub-surrounded playground and sand-court for babies and small children. At the other end of the house is a similarly secluded outdoor gymnasium for girls. Lastly, between the administration house and the northern mall and street, there will be found an open lawn, shut off from the malls by banks of shrubbery and surrounded by a path with seats where mothers, nurses and the public generally may find a pleasant resting-place.

Plans for those larger public domains, in which scenery is the main object of pursuit, need to be devised with similarly strict attention to the loftier purpose in view. The type of scenery to be preserved or created ought to be that which is developed naturally from the local circumstances of each case. Rocky or steep slopes suggest tangled thickets or forests. Smooth hollows of good soil hint at open or "park-like" scenery. Swamps and an abundant water-supply suggest ponds, pools or lagoons. If distant views of regions outside the park are likely to be permanently attractive, the beauty thereof may be enhanced by supplying stronger foregrounds; and, conversely, all ugly or town-like surroundings ought, if possible, to be "planted out." The paths and roads of landscape parks are to be regarded simply as instruments by which the scenery is made accessible and enjoyable. They may not be needed at first, but, when the people visiting a park become so numerous that the trampling of their feet destroys the beauty of the ground cover, it becomes necessary to confine them to the use of chosen lines and spots. These lines ought, obviously, to be determined with careful reference to the most advantageous exhibition of the available scenery. The scenery also should be developed with reference to the views thereof to be obtained from these lines. This point may be illustrated by assuming the simplest possible case, namely, that of a landscape park to be created upon a parallelogram of level prairie. To conceal the formality of the boundaries, as well as to shut out the view of surrounding buildings, an informal "border plantation" will be required. Within this irregular frame or screen the broader the unbroken meadow or field may be, the more restful and impressive will be the landscape. To obtain the broadest and finest views of this central meadow, as well as to avoid shattering its unity, roads and paths should obviously be placed near the edges of the framing woods. In the typical case a "circuit road" results. It is wholly impossible to frame rules for the planning of rural parks ; local circumstances ought to guide and govern the designer in every case ; but it may be remarked that there are few situations in which the principle of unity will not call for something, at least, of the "border plantation" and something of the "circuit road."

Within large rural parks economy sometimes demands that provision should be made for some of those modes of recreation which small spaces are capable of supplying. Special playgrounds for children, ball or tennis grounds, even formal arrangements such as are most suitable for concert grounds and decorative gardens, may each and all find place within the rural park, provided they are so devised as not to conflict with or detract from the breadth and quietness of the general landscape. If boating can be provided, a suitable boating-house will be desirable ; the same house will serve for the use of skaters in winter. In small parks economy of administration demands that one building should serve all purposes and supply accommodations for boating parties, skaters, tennis-players, ball-players and all other visitors, as well as administrative offices. In large parks separate buildings, serving as restaurants, boat-houses, bathing-houses and the like, may be

allowable. It is most important, however, to remember that these buildings, like the roads and paths, are only subsidiary, though necessary, adjuncts to the park scenery; and, consequently, that they should not be placed or designed so as to be obtrusive or conspicuous. Large public buildings, such as museums, concert halls, schools and the like, may best find place in town streets or squares. They may wisely, perhaps, be placed near, or facing upon, the park, but to place them within it is simply to defeat the highest service which the park can render the community. Large and conspicuous buildings, as well as statues and other monuments, are completely subversive of that rural quality of landscape the presentation and preservation of which is the one justifying purpose of the undertaking by a town of a large public park.

That the man who thinks out the general plan of a park ought to have daily supervision of the working out of that plan is undoubtedly theoretically true. It is impossible to represent in drawings all the nice details of good work in grading and planting, and yet no work is more dependent for its effect upon finishing touches.

On the other hand, however desirable the constant oversight of the landscape-architect may be, it is impracticable under modern conditions. The education of a designer of parks consumes so much time, strength and money that no existing American park commission, unless it be that of New York, can as yet afford to engage the whole time of a competent man. Consequently it is the usual practice for the landscape-architect to present his design in the form of a drawing or drawings, and to supplement the drawings by occasional visits for conference with those in immediate charge, by descriptive reports and by correspondence.

The prime requisite in the resident superintendent of park work is efficiency. Naturally enough, most of the superintendents of parks in the United States have been trained either as horticulturists or as engineers, but it is not necessary, or even desirable, that such should be the case. Probably the best results will be achieved by men who, possessing the organizing faculty and a realizing sense of the importance of their work, shall, with the assistance of an engineer and a plantsman, labor to execute faithfully designs which they thoroughly understand and approve.

Most men of specialized training, such as architects, engineers and all grades of horticulturists, stand in need of an awakening before they are really competent to have to do with park work. Each has to learn that his building, his bridge or road, his tree or flower, which he has been accustomed to think of as an end in itself, is, in the park, only a means auxiliary and contributive to a larger end—namely, the general landscape. It is hard for most gardeners to forego the use of plants which, however lovely or marvelous they may be as individuals, are only blots in landscape. It is hard for most engineers to conform their ideas of straightforward construction to a due regard for appearance and the preservation of the charm of scenery. Neatness of finish in slopes adjacent to roads is not sufficient; such slopes must be contrived so as to avoid formality and all likeness to railroad cuts or fills. Road lines and grades which may be practicable in the ordinary world are to be avoided in the park, because the pleasure of the visitor is the one object held in view. Roads, walls, bridges, water-supply, drainage and grading—such of these works as may be necessary are to be executed with all technical skill, as in the outer world; but the engineer in charge should be a man who will see to it that the work is done with constant regard to the object of a park as distinguished from the object of a city street or square or railroad.

Similarly, the park planter should be a man capable of holding fast to the idea that the value of a rural park consists in landscape, and not in gardening or the exhibition of specimen plants. Guided by this idea, he will avoid such absurd traces of formality as the too common practice of planting trees in rows beside curving driveways. In devising necessary plantations he will give preference to native plants, without avoiding exotics of kinds which blend easily. Thus, where a Banana would be out of place, the equally foreign Barberry, Privet or Buckthorn may be admissible and useful. Influenced by the same principle, he will confine flower-gardening to the secluded garden for which space may, perhaps, be found in some corner of the park.

Nothing, at first thought, would appear easier than to arrange a few trees in a beautiful group, yet experience has taught us that the generality of persons, in their first essays in ornamental planting, almost invariably crowd their trees into a close, regular clump, which has a most formal and unsightly appearance, as different as possible from the easy-flowing outline of a natural group.—*Downing.*

When is *Rhus toxicodendron* Most Active?

I BELIEVE it is generally assumed that the most active part of Poison Ivy is the leaves; at least, they are the only officinal part of the pharmacopœia, and it is from them that Professor Maisch obtained the volatile toxicodendric acid, supposed to be the poisonous principle. One would, therefore, hardly expect cases of poisoning in the early spring or before the leaves are well developed.

The plant abounds on this island. On April 29th a young soldier of this garrison presented himself with well-marked symptoms of dermatitis venenata affecting the arms and face; I could hardly believe that at this early date poisoning by *Rhus* was possible, and, therefore, inquired into the circumstances. I found that the patient had, with several comrades, been hunting snakes under rocks covered with the *Rhus*-vine, and that two of these comrades were similarly affected. Two or three days later a little girl who had been playing in the vicinity of the same rocks developed the usual characteristic eczematous rash, and doubt was no longer possible. At the time these cases were contracted the vine was (and is mostly still at this writing) perfectly bare; no leaf was visible and the buds were only just beginning to swell. We are, therefore, forced to the conclusion that the poisoning was produced by the stem—that is, by the active principle, presumably, contained in the young sap exuding or evaporating through the bark. The little girl mentioned above was much exposed to the *Rhus* during the whole of last summer without ever being poisoned. Does it follow, therefore, that it is more active in the early spring than later in the season, and that the poisonous principle is, at least, as much in the stem as in the leaves? As this question can only be solved by the comparison of many experiences, I submit it to the readers of GARDEN AND FOREST in the hope that they will make a record of their own observations in its columns.

V. Havard.

In the Pines.

FOR more than a quarter of a century vegetation has never been so backward in the Pines as it is this year. The birds, too, were very tardy in coming, but they are all here now in full force. Both the Baltimore and Orchard orioles are specially abundant. We almost despaired of our catbirds, for not until the 6th of May did they make their appearance in our neighborhood. The thrushes, vireos, wrens, orioles and many others were all here before them, which is very unusual. The winter birds, too, were slow to depart. The whitethroats were still with us the first week in May, and I saw now and then a junco lingering with them after the main body of these birds had gone.

On the 10th of May Apple-trees were still in bloom, but everything is now pushing so rapidly that by the first of June no marked difference in the season of our fruits and flowers will be noticed.

The Pines are beautiful now with Andromedas and the various Huckleberries, and the Sassafras is in full flower and giving a delicious spicy fragrance, together with the Bayberry, which is crowded with fertile catkins, and the fragrant new leaves are rising above a setting of old ones, which seem loath to give up their hold to this new generation. I see no appreciable effects of the severe winter on any of the evergreen plants, shrubs or trees in the Pines. This, no doubt, is largely due to the protective snow which was unusually deep during the coldest weather. The foliage of our charming Pyxie and the Arbutus is both more luxuriant and fresher looking than usual; they are out of flower, but the little Wind Anemone is still in bloom, and also numerous Violets. The Wild Strawberry almost carpets the ground with white in some places.

Large clumps of Euphorbia Ipecacuanhae are showy in white sandy places, with dense masses of purple foliage and greenish flowers. The wild Columbine is swaying its graceful flowers on its slender stems, and the wild Lupine, with its straight, upright spikes of blue flowers, is in striking contrast.

Almost every year the Pines are invaded by some wandering plant from foreign parts, which settles down and makes itself at home among the old inhabitants. This spring, for the first time, I see the *Sherardia arvensis* has become a fixture on our roadsides. It is welcome, as it is a little delicate thing with whorls of six small leaves around the square stems, and small blue flowers surrounded by a thick involucrum. This pretty plant can never become a pest, like its European relative, *Galium Mollugo*.

Pyrus arbutifolia is in flower, as well as some belated specimens of *Amelanchier*, but the latter is mostly in fruit, and promises an abundant harvest. The Swamp Maples are handsome with thick clusters of flaming red keys, and it will not be long before the brilliant Laurel and the Magnolia and *Xerophyllum*, with many other attractive flowers, will amply repay excursions in the Pines.

In the garden a white single Rose, one of the *Rugosa* type, commenced blooming on the 10th of May, and is now white with large beautiful roses. This is one of Mr. Dawson's plants. Other single white Roses in the garden are from two to three weeks later than this.

Great clumps of the German Iris are making a good display in the border, and some of the more choice Columbines are very attractive. But for brilliant color there is nothing better than a mass of scarlet Poppies, which are now in all their glory.

Foreign Correspondence.

Primulas.

THE genus *Primula* has a special fascination for horticulturists, a large number of species being included in our popular plants for the Alpine garden, while others are valued as pot-plants for cultivation in the conservatory. The Royal Horticultural Society holds a special exhibition of *Primulas* every year, accompanied by the reading of papers and discussions by specialists, which are of sufficient interest and importance to be called a Conference. At the exhibition this year a large number of plants were shown in flower, and papers were read by Mr. Baker, F.R.S., and others. Although the season has been most unpropitious for plants of the nature of alpine *Primulas*, yet the collections shown were almost, if not quite, equal to those of previous years. The *Auriculas* were well represented, and, as usual, received a large share of attention from the laity, who are, as a rule, uncertain whether they ought to admire or be amused by such quaintly colored flowers. Polyanthus are not popular in English gardens nowadays, and yet there are few herbaceous plants that will produce such an effective display of brightly colored flowers as these do in spring under the most ordinary treatment. But after all, the species, true and undefiled, are the élite of *Primulas*. Mr. Douglas showed a first-prize collection of twelve, which were a delightful picture; they were *P. mollis*, *P. Japonica*, *P. rosea*, *P. denticulata*, *P. verticillata*, *P. Cashmeriana*, *P. floribunda*, *P. Auricula*, *P. obconica*, *P. amœna*, *P. intermedia* and *P. decora*. These are all first-class garden-plants. One of the most charming corners in the rock-garden at Kew just now is a peat-bog of about four square yards filled with tufts of *P. rosea*, all in full flower, and as bright in its rose color as the *Chionodoxa* was in its blue a few weeks ago.

A list of the species of *Primula* in cultivation in English gardens would comprise at least fifty. There were thirty in flower in the Alpine house at Kew a few days ago. Mr. Baker, in his interesting remarks on the botany of the *Primula*, said that whereas twenty years ago the number of species known was between seventy and eighty, we now know about one hundred and fifty. The increase is largely due to discoveries in India and China. To quote Mr. Baker's own words: "We have now about one hundred and fifty species, of which, in round numbers, fifty are Chinese and Japanese, fifty are Himalayan and the other fifty are spread through Europe, northern Asia and

America." There are some distinct and handsome plants among the new discoveries in western China, which, however, have still to be introduced into cultivation. It would be worth the while of some enterprising nurseryman to send a collector into the districts made botanically famous by the missionaries, David and Delavay, and by Dr. Henry, many of the plants collected in Yunnan, etc., by them being such as would find general favor with horticulturists.

A paper by Mr. Self-Leonard, an enthusiastic trade-grower of Alpine plants of all kinds, dealt with the cultivation of *Primulas*. He divided them into three classes: (1) Species for the greenhouse, comprising *P. obconica*, *P. Sinensis*, *P. mollis*, *P. verticillata*, etc.; (2) large, strong-growing, hardy species, generally of the easiest culture, and comprising such noble garden-plants as *P. denticulata*, *P. Japonica* (an excellent plant for massing under trees), *P. capitata*, *P. Sikkimensis*, *P. Stuartii*, etc.; (3) the smaller and choicer Alpine species. For these he claimed a style of beauty altogether their own, which made their separation from their coarser brethren, both in the garden and in the exhibition hall, essential.

The cultural requirements of the plants of the third class were not, in Mr. Self-Leonard's opinion, of a special character, but, broadly speaking, they thrive under the same treatment as the *Auricula*, except that they do not require so complete a rest in midwinter, and at other times they do not need the continuous care and studied culture necessary to produce good *Auriculas*. Protection from the excessive wet in winter and spring rather than from cold is needed, most of them enjoying the low winter temperature if kept dry. On the other hand, many of them are all the better for protection from summer heat. The cooler climate of northern Europe always suits *Primulas* better than that of the south; for instance, they grow better in Scotland than in most parts of England.

The soil recommended was loam with a little sand, rather heavy than light, and an avoidance of peat in every case. A chalk soil is not, in his opinion, essential to the culture of any *Primula* and is poisonous to some of them. "Experience conclusively proves that those alpine *Primulas*, which, in nature, are only found on calcareous soils, can be easily grown in our gardens without a particle of chalk or lime in the soil." Mr. Self-Leonard, like all experienced cultivators, attaches comparatively little importance to the soil. He condemns "nostrums" and commends an intelligent interpretation of nature's teaching by the light of the cultivator's experience.

A third paper by Mr. Douglas on the *Auricula* dealt chiefly with their cultural requirements if intended to win prizes at exhibitions. He condemns indiscriminate crossing, especially between plants of the different sections, a bastard, inferior in all respects to its parents, being generally the result. The *Auricula* has had its devotees in England for about three hundred years, but only during the last century have the show varieties been classified according to the variegation or coloration of the flowers. Thus now we have (1) green-edged varieties which have white centres, black or blackish maroon zones and a margin of dark green; none of the plants in this class have powdered leaves; (2) gray-edged varieties, characterized by a thick coating of white farina on the outer margin, through which the ground color partially shows; (3) white-edged varieties, in which the powder on the margin is thick and uniformly white; (4) selfs, which have white eye-like centres and an unshaded margin of blackish maroon, purplish blue or red; in fact, any color that can be obtained, but it must be clear and unshaded. The meanness of the foliage in some of the varieties is so excessive that they are known in some localities as the "Dusty Miller." Mr. Douglas exhibited a fine specimen of *Primula auricula* grown from a little plant collected on the Swiss Alps fifteen years ago, and which he has had under garden-culture in rich soil ever since. Although, as he says, it had increased a hundredfold, it had not altered in the slightest in the size, form or color of the flowers. In

breeding new sorts, Mr. Douglas, after carefully selecting his breeders, considered himself lucky to get one seedling in a hundred that was worth growing for further trial. This applies only to the show or edged Auriculas, seedlings of the alpine varieties being generally of good quality and far less variable. Of course, all the named varieties are propagated by offsets and division. The seed should be sown as soon as ripe, usually about midsummer, and kept in a cool shady place. It germinates freely in the following spring, and the seedlings are pricked off as soon as they are large enough to be handled with safety. They are again potted into single pots, flowering, as a rule, in the second year from the sowing of the seeds. As a rule, a full-sized plant can be grown in one year from the seed-pot or from an offset. The offsets are planted in small pots and kept under shaded hand-lights till well rooted. The right season for repotting is May, the soil to use is good loam, and the position for the plants during the summer is in an airy frame on the shaded or north side of a building or wall. Mr. Horner has said that many people failed with Auriculas because they would set them out under garden-hedges, much to the enjoyment of snails and caterpillars, or keep them in cold damp pits or even down in areas. The successful grower has cool, light, airy houses or frames for them, and with these conditions, plus an intelligent knowledge of the nature of the plants, no department of floriculture yields greater or more lasting pleasure than that of Auricula growing.

London.

W. Watson.

Plant Notes.

AKEBIA QUINATA.—This vigorous twining plant is generally used for the covering of fences, arbors and the like, and it will quickly spread over large surfaces. But while it is most useful for that kind of work, it is also interesting when trained as an upright bush on a border or lawn, or when allowed to ramble over some shrub which is of little value. The prettily shaped leaves, which are digitate, are unlike those of most other vines, and they hold their shape and color well into the winter. The flowers, while lasting only a short time, are exceedingly pretty; the female flowers open first, and are more showy than the male flowers, being of a rich claret color, and two or three times as large as the others. They possess the additional merit of being very sweetly scented. A good way to train the plant to a bush form is to stick a few good stout tree branches in the ground; it will soon ramble over them and make a most beautiful object. The reason that this vine does not ripen fruit more frequently is probably owing to the fact that it flowers so early in the year, and that it produces the female flowers first, and these are nearly past before the males have had time to ripen their pollen. Occasionally, however, individual plants in this country and Europe produce fruit. In Japan its long, slender, pliable shoots, which are of uniform size throughout, are much used for wicker-work and even for baskets, trays and sun hats. Cuttings of the ripened wood put in a cold frame about the beginning of September will root quickly. The plants need considerable sunlight for their best development.

EXOCHORDA GRANDIFLORA.—This Pearl Bush, as it has been aptly called, is now altogether the most striking shrub in Central Park, although most of the specimens there have been allowed to grow into disagreeable open shape, which, together with thin foliage, makes a rather unattractive plant when out of flower. In New England this is not a long-lived shrub, and rarely attains a height of more than six or eight feet. South of this it becomes a small tree, or a shrub from fifteen to twenty feet in height. If cut in hard after it flowers every year it can be held to something like a compact shape, but if left to itself it has a better effect with some lower-growing shrubs massed in front of it to hide its naked stems. This is by no means a new shrub, having been known to cultivation for nearly half a century,

but for some reason it has never become as common as its near relatives, the shrubby Spiræas. Its great beauty consists in its large flowers, which appear with the leaves in long axillary racemes. They are borne in great abundance and are of a dazzling white. Large plants in this latitude produce seed freely, so that the plant is readily propagated in this way.

LILY OF THE VALLEY, FORTIN'S VARIETY.—This is a variety of French origin, and though it was distributed a few years ago by Peter Henderson & Co., and perhaps others, it does not seem to have created much of a stir, and it is not much grown in American gardens. It is a noble variety, much more vigorous and larger in all its parts than *Convallaria majalis*. The stem is tall and is clothed with flowers over twice the size produced by the ordinary variety under the same treatment. The bells are of the purest white.

IRIS STATELLÆ.—This is a Sicilian variety of *Iris lutescens*, and is one of the most attractive Irises, of medium height, which flowers at this time. It has large prominent standards, tongue-shaped and smaller reflexing falls. The flowers are of a pearly-white color, of very fine form and most distinct. It is a fine garden variety and excellent for decoration.

New or Little-known Plants.

A Blue Water-lily from Mexico.

THE handsome Water-lily * figured on page 206 was collected by Mr. T. S. Brandegee near Mazatlan, Mexico, in November, 1893. The flowers, which vary somewhat in size, are sometimes fully six inches in diameter and are of a pale blue color. The stamens are yellow, with long anthers and minute tips. The leaves are nearly orbicular, with few teeth, greenish above, with a few blotches, and of a dark purple beneath. The flowers were obtained from a small pond in an enclosed pasture containing about a hundred plants. Although those were the only specimens seen, the plant was reported to grow in abundance about the neighboring river. I am not quite sure of the species, but it appears to be nearest *Nymphaea elegans* of Hooker, which was figured in the *Botanical Magazine* in 1851, table 4604. Mr. Brandegee's specimens agree almost exactly with this figure, except that the flowers are considerably larger. *N. elegans* has until recently been one of our rarest species, and for nearly forty years remained uncollected (*Bull. Torrey Bot. Club*, xv. : 14). In late years it has been frequently sent in by such well-known collectors as Mr. C. G. Pringle, Mr. G. C. Nealley and Mr. J. E. Bodin. The original specimens of *N. elegans* are said to have come from New Mexico, but all our recent collections have been made from Texas. The species has not been reported from the west coast of Mexico, and this fact, taken in connection with the difference in size of the flowers, leaves some doubt as to above reference of these specimens. It certainly belongs to no other Mexican species with which I am familiar.

Cultural Department.

The Rock Garden.

THE winter, just past, proved to be one of the most trying of recent years for vegetation on rock-work. On the first of May the plants seemed two weeks behind time, but the dry, hot weather of the past week has hurried all spring flowers into bloom, so that everything has caught up. We cannot complain of many specific losses, but much injury has been

* *Castalia elegans* (Hook.) Greene, *Bull. Torrey Bot. Club*, xv. : 85 (1888).—*Nymphaea elegans*, Hook., *Bot. Mag.*, t. 4604 (1859).

Leaves nearly orbicular, a little longer than broad, $\frac{1}{2}$ by $\frac{1}{2}$ inches, with 7 or 8 radiating nerves on each side of the midrib, otherwise it is somewhat pubescent above, dark purple beneath, the margin nearly entire with very small sharp teeth; lobes overlapping at base except their apices; flowers a rich blue in diameter, light blue; petals brownish at base, light green above with purple blotches, light blue within; outer sepals without a scarious intermediate; inner sepals nearly like the petals; petals 12 to 20, oblong, abrupt; ramification numerous, about 75 filaments broad, yellow; anthers longer and narrower than the filaments, yellowish; the prolonged connective a mere tip, at most $1\frac{1}{2}$ lines long.

done to many fine plants which have usually come through in good condition. It was apparently during the ice storms in February when the greatest damage was done, rather than by severely cold weather at any time, though low temperature was continuous. All the Moss Pinks, *Phlox subulata*, in exposed situations, were much burned. Many European species of *Dianthus*, *D. alpinus*, *D. neglectus*, *D. glacialis*, *D. subcaulescens*, *D. plumarius* and *D. armulatus* (*Cyclops*) are dead entirely. *D. arenarius*, *D. cœsius* and *D. deltoides* appear to be the only ones which have come through uninjured. *Silene Schafta* is among the lost. *Primula rosea* has stood uninjured for two seasons. Now only a few seedlings remain, which evi-

canes of this handsome trailing Rose sixteen feet long and twined them about the trunk of a young Walnut-tree. These stems are now breaking freely more than six feet away from the ground. No better testimony to the extreme hardiness of this beautiful Rose could be desired. We have it trailing over rocks on a rather steep slope. It is appropriately placed, but the space devoted to it is limited. It is clearly a subject for a sunny bank in the wild garden, where it can roam un molested. Bushes of *Andromeda Japonica*, which from some reason or other have never bloomed before, are flowering well this spring. They have always been protected with loose litter, and every autumn they have been well set with drooping racemes of

Fig. 31.—A Blue Mexican Water-lily.—See page 205.

dently have been protected by other low-growing plants among which the seeds had been scattered. Of the *Megasea* section of the genus *Saxifraga*, *M. purpurascens*, is badly burned, while *M. cordifolia* is scarcely touched; the immunity of the latter may be due in part to a more protected location. Many plants belonging to the mossy group of *Saxifrages* are missing, and what are left are considerably browned.

On the other hand, bushes of the Dawson Rose, with canes from eight to ten feet long and arching upward from two to three feet, are not at all touched. Stout plants of the Japanese form of *Rosa multiflora* are green to the ends of the branches. *Rosa Wichuraiana* looks as fresh as it did last autumn. I found

flower-buds. This is indeed a handsome shrub for planting where it can have protection from the direct rays of the mid-day sun. Several bushes of the Polyantha Roses, White Pet Mignonette and Clothilde Soupert, are growing in recesses between the rocks. It may be they are not appropriate subjects for the rock garden, but they have always done well here and have plenty of good green wood eighteen inches or more above ground, while those in a bed especially prepared for them and protected every winter with litter, are killed to the ground. *Ramondia Pyrenaica* came through better even than it did last season. White *Asphodelus lutea*, never supposed to be hardy, is throwing up a strong flower-spike. Sal-

via argentea is making a good spread of its handsome silky foliage for the third year, and is thus proving a good perennial.

Nearly all the Narcissi are over. Jonquils and the old form of *N. poeticus* are all that remain in bloom. The variety *Ornatissimus* comes and goes with *Horsfieldii*, *Emperor* and *Sir Watkin*. Usually the Poets' Daffodil stays with us until the end of the month, when large quantities are used in the ceremonies of Decoration Day. Siberian Squills, *Chionodoxa* and *Snowdrops*, *Galanthus*, all low-growing, early-flowering bulbs, and splendid for massing, are now forming their seed-capsules. It might be worthy of note that all these early spring bulbs can be easily increased from seeds. The capsules will be ready to gather in about three weeks, just as soon as the seeds turn black. If left longer they burst, scattering the seeds all about. They should be sown at once, but will not germinate until the following spring. The young bulbs should be allowed to grow one season in the seedling-box, and transplanted after the ripening process in August. After another season's growth they will be ready for permanent quarters. By being let alone—that is, being simply weeded, instead of hoed—our Siberian Squills have increased fourfold during the last five years, seedlings coming up every spring, outside the original patch, in batches like young Onions.

Admirers of alpine plants, who can find time to weed instead of hoe, will find their work quite full of interest. It will, however, often be our duty to weed out some beautiful plants. We soon lose all affection and admiration for a plant, however beautiful, when once it becomes aggressive. Years ago we had several species of *Potentillas*. All had handsome Strawberry-like leaves and yellow or brown, saucer-shaped flowers, but they spread so extensively that we have been weeding them ever since. *Alyssum saxatile* and *Dianthus deltoides* are other plants which need to be thinned considerably to be kept within bounds. *Viola cucullata*, in white, purple and striped, rapidly spreads. Whatever we find inspiring we allow to bloom when they do not interfere with other plants, and pull them out when summer comes. On the contrary, there are others we can scarcely have too many of. *Mertensia Virginica* is one of these. Just now its nodding cymes of incomparable blue are springing up everywhere between the rocks and along the paths, where really they ought not to be. The rock garden must not be artificial, so we leave them. Periwinkles, now in splendid bloom, are growing out into the paths, compelling one to make a detour; most of us would rather do this than cut it away. *Campanula Carpathica*, *C. turbinata* and *C. caespitosa* are other plants which come up in all sorts of places, and we are loth to disturb them. *Oenothera Missouriensis*, once planted on the higher levels, is spreading, step by step, down the slope. It is a handsome trailer, and ought to grow so as to overhang a ledge, where it can be seen from below. The Japanese form of the Chinese Bell-flower, *Campanula pumila Maresii*, whose clear blue flowers associate so well with the dwarf Golden-rods in autumn, is another desirable plant which we like to see spreading itself. Alpine and Iceland Poppies, now hybridized, and with double forms, appear in the clear gravel paths, and grow there as vigorously as anywhere. Our native Columbine, *Aquilegia Canadensis*, though rather intrusive, is, nevertheless, one of the most welcome spring-blooming plants. Occasionally purple forms appear, showing that some late-blooming plant of the species has been hybridized by some of the earlier-flowering plants of *A. cærulea*. I do not, however, think any beauty comes from this cross, and feel disposed to weed them out, lest in time too many of them appear. *A. Skinneri* takes care of itself fairly well, but the Siberian, *A. glandulosa*, makes no headway, and dies out after a year or two.

T. D. Hatfield.

About Tulips.

THE ruin of the Tulips in flower last week by a few days of hot weather, followed by rains, is a thing to be expected any year. The conditions should serve as a warning against growing only one class of Tulips or those which flower at the same time. Those who are tempted into making barbaric masses of color by planting a bed of Tulips, all of which are certain to flower at once, are apt to secure a short-lived, if vivid, pleasure. When one has Tulips of all sections he not only has a display extending over a number of weeks, but a storm or hot wave has only a temporary effect, and the pleasure is never brought to a sudden stop by bad weather.

According to the Tulip fanciers' standards there are very many with bad form and worse color, but if one is not versed in points, and simply enjoys color, there are not many very ugly Tulips, though there seem to be many of flimsy texture. Except *Tulipa Greigii*, which stands alone for beauty and dis-

tinctness, the original species are not as handsome as many of the Dutch hybrids, yet there is a character and distinction about most of the species which makes them attractive and pleasing garden-plants, and they often serve as a foil to the regularity and formality of the hybrids. Of course, one must except the Parrot Tulips from the formal ones. As a rule, I think it will be found that the species, except, possibly, *T. Greigii*, are more reliable and regular in flowering from year to year than the hybrids, which, under rude treatment, soon run out. One often finds Dutch hybrids with distinct traces of *T. sylvestris*, but this species for a mass of yellow is unsurpassed. It is of a good rich color, is pleasantly fragrant and of rapid increase. An Italian form of this sent out by Dammann last year was very good. *T. Schamki* is a beautiful Tulip, white flushed rose, which gives one the earliest flowers, though it is said by Nicholson to be a synonym of *T. Gisneriana*, which "is evidently the original stock of most of the late-flowering kinds."

Other species there are in the garden, but none so distinct from the ordinary kinds as the small low-growing Asiatics, which are so suitable for a rockery. These have small flowers of various colors, sometimes with short scapes and broad leaves, as in *Tulipa ciliatula*, and again taller scapes and narrow leaves, as in some forms lately collected by Mr. Whittall on the Madcan and Naz Daghs. It is now the season of the late-flowering *Bybloems*, *Bizarres*, etc., the old favorite garden Tulips, which possess dignity of stature and richness of coloring of a quiet character. Mr. P. Burr has lately been busily collecting some forms of these from old English gardens, remnants mostly of English seedlings. A collection of these at present in flower contains many fine forms; on the whole, rather brighter than the Dutch kinds, though among these are colors which can be spared.

Elizabeth, N. J.

J. N. Gerard.

Narcissus Notes.

THE flowering season of *Narcissus* is nearly past now, and only the midseason and late varieties of *N. poeticus* remain to bloom. The experience of this year has not added to the knowledge of the various kinds in cultivation. One thing is certain, however, in this country, that if the climate or soil does not suit any particular kind of Daffodil it will be surely apparent the spring following the first summer's growth in a weak start and sparse flowering, while hardly a trace of the plants will be left the next year. Of those that have disappeared I cannot call to mind a single kind that I would care to have again, and the best sorts thrive and increase at a surprising rate. Mr. Gerard said, in his last notes on this subject, that a bad memory is a good thing to carry at times in the garden, and this is forcibly brought home to me at times when near the Daffodil beds. It has often been noted in these columns that during summer these beds are filled with annuals such as *Asters*, *Mignonette* and others, and last fall when these were past a workman was instructed to clear off the remains, and in his anxiety to clear away everything he pulled up about seventy *Narcissus* labels. This will explain why a detailed list of losses cannot be given. The better-known and larger-flowered varieties can, of course, be identified, but the bulbs belonging to the *Burbidgei*, *Leedsii* and *incomparabilis* sections had better be lifted and naturalized in the Grass, as has been done with surplus stock of the Poets' *Narcissus*. In places where many spring-flowering bulbs are used there is abundant room for planting the cheaper kinds in the sod where the grass is not cut until midsummer. We have tried this plan with success in an orchard under the Apple-trees. No care was taken to prepare the soil or even disturb the sod; a spade was thrust into the soil and a bulb put in each place, and I am inclined to believe that if the newer Spanish kinds had been treated in this way they would have lived longer and flowered well, while under the treatment given to the stronger-growing garden varieties they soon died; perhaps from cold, as we never cover the beds in fall unless the bulbs are planted late; it may have been from too generous treatment, as has been suggested.

We have been particularly fortunate in having the so-called white varieties live and do well. *Albicans*, *Colleen Bawn*, *Moschatus*, *Leda*, *Mrs. J. B. M. Camm*, *William Goldring*, have all done well and flowered each year, but we take care not to manure them in fall as we do the others that are grown for cut flowers.

One of the gems of the border is the Irish form of the double Jonquil, with the astonishing name of *Narcissus odorus plenus Hibernicus*. We have had it four years, and it never fails to bloom, and increases each year. On the contrary, *N. capax plenus* has disappeared. *N. biflorus* is another of the

uncommon kinds that do well. It is very late in blooming, and resembles the Tazetta section in general appearance, having several flowers to each stem, and these fragrant. Muticus, the last of the Trumpet Daffodils, has taken longer to die than any other, and there are still a few left. These were evidently collected bulbs, as no two were alike, but they did not take kindly to cultivation. We have now a fine reserve stock of bulbs to dig from to grow in pots in winter. Home-grown stock is far preferable to any that can be imported, and after flowering these are replanted in among the shrubs, and in two years are as good as ever. Those who intend to plant Daffodils will do well to make out a plan of the bed after the work is completed, and keep it for reference. Had this been done in our case the loss of our labels would have been less of a disaster. No one can go amiss in planting such kinds as Emperor, Empress, Horsfieldii, M. Foster, Grandee, Countess of Annesley, Princeps, Golden Spur, Obvallaris, Sir Watkin and Henry Irving. Maximus and Ard Righ have not done so well as we anticipated, and have now almost died out.

Border culture has one disadvantage in that after every April shower the purity of the flowers is marred by the earth that has been splashed over them, and there seems to be no way of preventing this except by planting in the grass; this we shall try on a much more extensive way next fall. Regular masses should be avoided, or the effect would be more or less artificial. I have seen acres of the common kind growing wild in pastures in the southern counties of England, and cattle do not seem to eat the foliage, or these wild Daffodils would have been extinct long ago.

South Lancaster, Mass.

E. O. Orpet.

Coreopsis grandiflora.—For cut-flower purposes or for a border plant there is nothing which bears yellow flowers to equal *Coreopsis lanceolata* and *C. grandiflora*. I was never aware of its value as a pot-plant until this year. We wintered a few plants in a cold frame in five-inch pots and brought them indoors about the middle of January, and a shift was given them to eight-inch pots about the middle of April, when the flower-stems were well advanced. Since the last week in April our plants have been loaded with flowers some three inches in diameter, borne on fine stems eighteen to twenty-four inches long. For cutting this *Coreopsis* is much superior to any other variety, and its easy cultivation should ensure its wider use as a pot-plant. We sow our seed in the open ground the last week in July, and those required for indoor use should be potted about the end of October.

Taunton, Mass.

W. N. Craig.

Dionaea muscipula.—This little plant, popularly known as Venus' Fly Trap, well deserves a place in the greenhouse. The ordinary observer may look on it only as a curiosity, but to the plant-lover it has a beauty all its own. The upper portion of the leaf, which constitutes the trap, is dilated into a two-lobed irritable limb, furnished at the margin with a row of long stiff bristle-like teeth. When a fly or other insect alights on the inner side of this portion it immediately folds up and holds the insect while it makes the least motion, but gradually assumes its normal position again after the insect is killed and ceases to struggle. It is of easy cultivation and does well in a greenhouse temperature and should be placed in a position where it will be shaded from direct sunlight, but at the same time have abundance of light and air. First place the plants in small pots half filled with crocks, using live sphagnum moss as potting material, then place the pots about six in a ten-inch pan, and pack them firmly around with sphagnum, place the pan in a saucer and keep this all the time filled with water.

Tarrytown, N. Y.

William Scott.

Saponaria ocymoides, a dwarf-growing perennial Soapwort, from the south of Europe, is one of the few really good rock-work plants which stand our hot summers; it has very pretty pink or red flowers, produced in such great profusion as almost to cover the foliage from view. Seed sown in the fall will give flowering plants for the following spring. Cuttings root well enough in a cold frame, but seedlings are preferable, as they form more bushy plants than those from cuttings.

Fritillaria imperialis aureo-marginata.—The variegated Crown Imperial is a most striking object now in the herbaceous border. The common kinds are handsome when well developed, but this form has, in addition to its flowers, beautifully variegated foliage. The Crown Imperials ought to have a place where they can remain undisturbed during the summer, as after flowering they soon die down to the ground. It is well to have the places where they are planted indicated by a good

stout label. As it is an early bloomer, this species is very liable to get hurt from cold winds, therefore a sheltered position is desirable.

Botanic Garden, Washington.

Correspondence.

Winter Storage for Tender Evergreens.

To the Editor of GARDEN AND FOREST:

Sir,—Two years ago I imported from England about a hundred tub plants for the decoration of my terraced garden. The invoice included *Cephalotaxus Fortunei*, *Cupressus Lawsoniana* and several garden forms, *Taxus elegantissima*, *T. baccata*, etc.; *Ilex crenata*, *Evonymus*, Box, Portugal Laurel, Holly and *Retinospora*.

This spring more than half of the plants are dead or dying, owing, I think, to faulty management during the winter. I shall esteem it a favor if some of your correspondents will enlighten me as to the best methods of winter storage and care of such plants. My storage-house is of brick, fifty feet by twenty on the floor and eighteen feet high, with perfect means of controlling light and temperature. The questions I should like to have answered are: Can the above-named plants be satisfactorily wintered in common? If yes, what should be the light and temperature of the storage-house, and the arrangement of plants with reference to sources of light and ventilation, and how much watering should they receive?

Weston, Mass.

Francis Blake.

[The above inquiry invites attention to the fact that there are many beautiful evergreens which cannot endure the outdoor rigors of a New England winter, but which in suitable quarters can be easily carried through the trying season, and then be most useful plants for decorating lawns and terraces in summer. The variegated Hollies, *Evonymus*, Yews and various forms of *Cupressus*, *Retinospora*, Laurel, Sweet Bay are all in this class. It should be understood at the outset that all these plants will stand a large amount of cold, and in the moister climate of Great Britain they very frequently go through periods when the temperature ranges very near the zero line. Owing to the better maturing of the growth here in fall there is no reason to doubt that the evergreens named above would endure even more cold here than in Great Britain; but our cold weather is often accompanied by winds of high velocity, while the sun is as high in our skies during February and March as it is in Great Britain in May and June. This combination of hardships is too formidable for these choice evergreens which have been developed under more equitable conditions of climate. An illustrative case is that of the common English Ivy, which is fairly hardy even here in Massachusetts if planted on a north exposure, but a southern aspect is sure death to it the first winter. Taking it for granted, then, that a frost-proof structure is not essential to these plants, the matter of providing a place of storage for them is much simplified. Ours are placed in the cellar under the coach-barn, where it freezes every winter soon after the advent of really cold nights; but once frozen, there is no thawing out until the month of March, and there is never any need of watering until after the plants are taken out-of-doors. As long as this complete rest is obtained without admitting air by means of ventilators, all goes well, but should the structure be actually frost-proof, it will be necessary to give air enough to bring down the temperature to from twenty-five to thirty degrees; it may go lower than the first, but never higher than the last-named figure until the time arrives to prepare to get them out in spring. Pure air is, of course, essential; asphyxia and dyspepsia are as common symptoms in the vegetable as in the animal world. If a cellar is used, perfect drainage must be secured and no deleterious gases that the plants cannot breathe should be admitted. An excess of ammonia from adjacent horse-stables, for example, might be fatal. The soil should be made porous by good drainage, and the admixture of charcoal and lime refuse with it is advisable on account of the purifying action of both these substances.

Tubs are the best receptacles for these plants, as the

wood is a good non-conductor; slate or earthenware will heat in the sun sufficiently to damage the roots in hot weather. Great care is necessary in the culture of plants in tubs to prevent the ingress of earth-worms. If the tubs be placed on the ground the moisture will attract them for a great distance, and the drainage will soon become clogged and ill health will follow. Wherever it is possible, as, for example, on terraces, it is best to place the tubs on masonry. If not, they should be elevated on bricks to give a circulation of air, and if earth-worms have already made an entrance they may be driven out by the application of clear lime water; it is possible to use the same lime to make several applications of lime water, as water will hold only a certain quantity of lime before becoming saturated. Of course, Ericaceous plants cannot be treated in this way. Lime water would be fatal to Rhododendrons, Kalmias, Andromedas, Leucothoës, and all plants that have the fine hair-like roots characteristic of the Ericaceæ.

If the foregoing essentials are carefully regarded there should be no difficulty in wintering any of the shrubs named by your correspondent. It is possible that some one of these, either in construction or treatment, has been lacking, and if it is supplied no further trouble will be experienced. For terraced gardens these shrubs are almost indispensable, and in some locations terraced gardens are indispensable.

E. O. O.]

Wayside Shrubbery.

To the Editor of GARDEN AND FOREST :

Sir,—I have just returned from a drive, rather more than half a mile of which was on a byroad, which means a narrow strip of wheelway somewhere between stone fences, which, by the law of the state, are set two rods apart. There is little travel on this cross-road, and, therefore, the roadmaster has kindly allowed its borders to take care of themselves for two or three years past. When the wayside shrubbery gets too aggressive he will go in some fine June morning with his axe and cut down some of the most vigorous trees and shrubs and burn them, but in a year or so the place will be as wild as ever. In this thicket the wild Plums have gone out of bloom, but the young Apple-trees which the birds have planted are still in flower, and the Scarlet Fruited Thorns are at their best. There are great masses of bright Pinxter-flowers, and the graceful racemes of the Choke Cherry are unusually abundant.

Of course, the leaves at this season are quite as beautiful as the flowers, and from the deep red of the young seedlings of Swamp Maples to the gray of the Dwarf Willows and the light yellow of the Sassafras there are tints without number. Wild flowers smile all along the sides of the road; Violets and Anemoneellas, Mandrakes, and, most beautiful of all, the Columbines, unite with the shrubberies to make pictures of rich and varied beauty, and new ones greet the wayfarer at every step.

No doubt the "inescapable joy of spring" makes everything look beautiful at this season, but this byroad will continue beautiful all summer long, and have fresh attractions every day in the way of foliage, flowers and fruit. I am writing of this simply to say that all through the hilly parts of our eastern states every road can be made just as beautiful if the margin of it is only left to take care of itself. Why should not societies similar to Village Improvement Societies be organized in townships to protect all this beauty instead of paying roadmasters for devastating every roadside? How many people are there who really believe if their attention is once called to the matter that naked stubs and stones and ground burned black is more beautiful than a natural growth of a wayside vegetation?

Denville, N. J.

M.

. Rhododendrons in a Hard Winter.

To the Editor of GARDEN AND FOREST :

Sir,—In reply to your inquiry as to the effect of the past winter on my Rhododendrons, I would say that they have not suffered to any considerable extent. The winter was not unusually severe here, the lowest record being ten degrees below zero, and yet it is true that in this vicinity many collections have suffered rather seriously. Every year my faith is strengthened in the theory that Rhododendrons are more apt to suffer in this country from drought in summer than from cold in winter. We do have a winter occasionally in which

plants are injured, but this is not always from serious cold; during the past year, for example, a large portion of the damage showed itself in the latter part of the winter, and it, therefore, seems probable that our bright sun in March sometimes scalds the foliage when it is covered with frozen sleet. For this reason I have made most of my plantation on the north side of a belt of evergreen trees, and I have found that these always suffered less than plants which have a southern exposure; and this is especially true of such varieties as are generally considered half-hardy. This year I noticed that large healthy plants of *Album grandiflorum*, for example, in a sunny and sheltered border have been quite killed, while varieties as tender as J. Walter and Kate Waterer, planted in the shade and only a few feet distant, are all right. I enclose a memorandum of some of the best varieties which I have been growing for the last few years, nearly all of which have not suffered in the least during the past winter, although a few of them have been slightly touched: A. Adie, Blue Bell, Hamlet, C. S. Sargent, Mrs. C. S. Sargent, F. L. Ames, F. L. Olmsted, James McIntosh, Sefton, P. Simon, Princess Mary of Cambridge, Silvio, Vauban, Duke of Teck, J. H. Agnew, Mrs. Heywood, Lady Grey Egerton, Bacchus, Lothair, J. Marshall Brooks, J. Walter, Kate Waterer, Mrs. John Clutton, Ralph Sanders, Mrs. Shuttleworth, Duchess of Sutherland, J. D. Goodman, Pelopidas, Countess of Normanton.

Wellesley, Mass.

Shy Wood Plants.

To the Editor of GARDEN AND FOREST :

Sir,—In an illustrated article sometime ago on *Phlox divaricata*, GARDEN AND FOREST speaks of it as somewhat rare, and though I find it quite common in the woods here I am at a loss to know how such a shy plant can hold its own for any length of time anywhere. It is never found except in part shade and in soil made almost entirely of leaf-mold, so light that in exposed places it would require the leaf and root fibers to keep it from blowing away. It lives the most precarious life in semi-cultivation, and I have always lost every specimen after two or three years. The partiality the garden-slugs have for *Phlox* has something to do with its disappearance, but it must be classed as tender, or perhaps uncertain is the better word, along with Bee Balm, Claytonia, Hepatica, and not a few others which cling to the woods, not probably from choice, but because one needs the winter protection and another the light soil afforded there, and also the freedom from the sod that drives them all from the fields.

Nearly all wood plants are obliged to flower in the early spring before the trees put out their leaves and live a semi-torpid life the rest of the season. Cannot some evolutionist show us how the rise of the sod-producing Grasses has not only driven them to the woods, but also changed their time of flowering to accommodate them to their condition of enforced seclusion?

Buffalo, N. Y.

Dictionary of Orchid Hybrids. By E. Bohnhof. Paris: Octave Doin.

This little manual contains a list of all artificial hybrids among Orchids which were known up to the beginning of the present year, with the name of their introducer and the date of their appearance. The plants supposed to be natural hybrids are also placed in the list, and tables are added to indicate the seedlings which have been obtained from each species. This will be a useful list for all who wish information as to the origin of hybrid Orchids, and those who are engaged in hybridizing will find it serviceable by showing in a compact form what has been accomplished with each species. It is proposed to publish a new edition of this dictionary every two years, so that the list can be kept as nearly up to date as possible.

Notes.

There is no more showy flower just now in the border of hardy perennials than the cut-leaved Peony, *Paeonia tenuifolia*, which blooms several days earlier than the ordinary garden varieties of *P. officinalis* and *P. albiflora*. The single-flowered variety, with its solitary dark crimson cup-shaped flowers on stems a foot and a half high, is much more rare

and rather more handsome than the double-flowered form, although the latter is very beautiful. These plants need nothing but fairly rich and deep soil and they will continue to flower year after year.

During the first week in May two hundred and twenty-four car-loads, amounting to nearly 64,000 boxes, of oranges, were sent from Riverside, in southern California. It is estimated that the value of the entire orange crop of the section which ships fruit from this town will sell for \$750,000.

The first small shipment of Peen-to peaches, from Florida, arrived last Friday, and regular supplies are expected this week and hereafter during the season. Fine Early Alexander peaches, grown under glass in Massachusetts, bring fifty cents each, and hot-house melons cost a dollar and a half apiece. The finest Porto Rico pineapples retail for one dollar each. Muscat grapes, from Cape Colony, are still coming in limited quantities, but the clusters are small, and persons who are willing to pay for grapes at this season prefer the more showy products of the hot-house.

In a paper on Cannas, read by Mr. James I. Donlan before the New York Florists' Club last week, he speaks of the American seedling Columbia as being of a new and distinct type and altogether a noble plant. It grows only from two to three feet high and is of a stocky habit, with large dark green foliage of leathery texture. The flower-spike often branches so as to give the effect of three or four trusses of bloom at once, each of these appearing as a separate spike. The color is a rich cardinal-red with a scarlet gloss toward the end of the segments, and the immense trusses of red flowers borne on plum-colored stalks give the plant a very distinguished appearance:

The first sweet corn of the season came from Bermuda by Monday's steamer, and was offered by Mr. Kelly, the leading dealer in Washington Market, at seventy-five cents a dozen. It was well grown, and after the voyage of thirty-six hours the husks and kernels looked as fresh as they usually do in warmer weather when coming from neighboring gardens. Parsnips, sweet potatoes and other winter vegetables of good quality may still be had, and, besides fresh products from the south, kohlrabi and most delicate cauliflower are brought in from neighboring hot-houses. All early spring vegetables are now in good supply, but the best asparagus, green peas and wax beans, with new squashes and cabbage from Florida, still command high prices.

The second annual exhibition of native flowers collected by the Science Class of the Normal College of this city, was made in the library of this institution during three days of last week. The collection was tastefully arranged on a half-dozen long tables, many species and varieties of wild flowers from eighty-two different genera being represented. The display of flowers was not only beautiful in itself, but it was also interesting and instructive in the scientific accuracy with which the flowers were arranged, each order being grouped by itself and each specimen being carefully named. Not the least interesting table was the one bearing specimens of Grasses, Mosses, Ferns and branches of trees in blossom. The exhibit was altogether creditable, and, besides its value to the students and collectors, showed to the visitors, what many of them had never realized before, the beauty and great variety of the native flowers now in bloom in this locality. Most of the specimens came from Pelhamville and Staten Island. An admission fee of fifteen cents was charged and this was to be for the benefit of the Alumnæ Kindergarten.

On the sidewalks the itinerant dealers are busy selling branches of Pinxter-flower, Dogwood and Black Haw, and even the expensive flower-shops are decorated with Mandrake, *Podophyllum peltatum*. Commercial flowers are very abundant, but they are of poor quality, and it is hard to get first-class roses and carnations. The best Madame Cusin roses bring only \$1.00 a dozen; Brides and Bridesmaids, \$1.50 a dozen; American Beauty, \$1.00 to \$5.00; Baroness Rothschild and its white sport, Mabel Morrison, \$3.00 to \$4.00; Ulrich Brunner, \$3.00 to \$5.00, and General Jacqueminot, which are more scarce than some other sorts, \$2.40 to \$4.00; Moss rose-buds are seen in most of the best stores, and these cost \$2.00 a dozen. Well-grown carnations of the Helen Keller, Dean Hole and Albertina varieties bring seventy-five cents a dozen, but the average price for good flowers of other varieties is fifty cents, and fairly good carnations may be bought on the street for thirty-five cents a dozen. A few paeonies have come, and some forced gladioli. Of Dutch bulbous plants a few Parrot tulips and late Poets' Narcissus are all that are left. One of the prettiest flowers now sold is the yellow Sweet Sul-

tan. Sweet peas and lily-of-the-valley are favorites, and in special demand at this season, and lilacs are offered at prices that are merely nominal.

A *Farmer's Bulletin*, just issued by the United States Department of Agriculture, gives many interesting facts about the cultivation and use of Sweet Potatoes. The most northerly state where this crop is extensively cultivated is New Jersey, although crops have matured at the experiment stations in Lincoln, Nebraska, and Geneva, New York. The Sweet Potato is most commonly propagated by means of buds from roots planted in hot-beds, and the shoots as they develop are planted in the field. Cuttings from these vines are often rooted and transplanted for the main crop. The plant rarely matures seed in the United States. Ninety days after the sets are transplanted early varieties will be ready to dig for use. The best growth is made in warm, sandy, well-drained, and even dry, soil. The greatest care in harvesting is necessary to prevent bruising the roots in handling, for the skin is very tender and wounded roots are sure to decay. They are best preserved by being kept in a temperature of seventy-five degrees for a fortnight after digging, and then lowering the temperature and keeping it during the winter at from fifty to sixty degrees in a dry atmosphere. Rather more than two-thirds of the weight of the Sweet Potato root is water. Three pounds of the roots afford as much dry matter as one pound of corn, but only about half as much protein. On sandy soil, however, more dry matter to the acre can be secured with a crop of Sweet Potatoes than with a crop of Corn. The young leaves and tender sprouts of the plant are sometimes prepared and eaten like spinach, and the vines, although they are usually left to decay in the field, can be profitably used as food for cattle. They are better fed green than cured into hay, and they cannot be successfully made into ensilage.

In Bulletin No. 87 of the Cornell Experiment Station, Professor Bailey presents a study of the Dwarf Lima Beans which have become so popular. These Beans have been derived from three types of the Pole Lima. The first of these types is the so-called Sieva or Bushel Bean, *Phaseolus lunatus*. Henderson's Dwarf Lima is a sport from this, the original plant having been found more than twenty years ago by a negro along a Virginia roadside. The Lima Bean of American horticultural literature comes from the variety *macrocarpus* of *P. lunatus*. There are two types of this Bean, the one known as the Potato Lima, with tumid or nearly spherical seed, the other as the Flat Lima, with large, soft, veiny seeds, tall growth and late maturity. The Thorburn, Kumerle or Dreer Dwarf is a form of the Potato Lima, and the Burpee came from a dwarf plant of the large White or Flat Lima. There is a fourth Dwarf, the Barteldes, from Colorado, which has little to recommend it for cultivation here. It is derived from *P. multiflorus*, the Scarlet Runner or Painted Lady, which is cultivated generally as an ornamental plant here, although the young pods and ripe beans are excellent for the table. These dwarf Limas are all valuable, since they are from two weeks to a month earlier than the Pole varieties. They are so productive that in the north it is possible to secure a greater total yield per acre from them than from the old varieties, since the plants require less room. We have often spoken of the relative value of these Beans. Henderson's is the earliest. The plant is compact, the most productive, and continues the longest in bearing, and the small, flat, clear white beans are of as good quality as any Sieva Bean, though not so rich and buttery as the true Lima. The pods also escape the mildew, which is often serious upon the late thick-podded sorts, and its combination of merits insures a place for it in every garden. Another Dwarf known as Jackson's Wonder is also of the Sieva type, differing from Henderson's in having the beans brown-speckled, the plant being rather less dwarf and compact and a trifle later. The Thorburn, Kumerle or Dreer Dwarf is a bush-plant with no tendency whatever to climb, only moderately productive, and rather late, its white tumid beans having the excellent qualities of the Potato Lima, which by many people is considered superior even to the large white Lima from which Burpee's Bush Lima is descended. This last is a true Lima, somewhat taller than the Thorburn, occasionally reaching a height of two feet, the flat seed as large as those of the Pole Lima; season medium to late, or about three weeks later than the Henderson, and about the same as that of the Burpee, and rather more productive than that variety. Mr. T. Greiner considers the Dreer Bush Lima as the best bean in quality, but he notices as a drawback to the usefulness of the plant that the pods grow so closely together and so near the ground that they are in danger of becoming soiled and rotted before the beans are fit to use.

The Debt of America to A. J. Downing.

WE can hardly realize that it was not until some years after the middle of the present century that any American city had begun to make provisions for a public park. New York already ranked among the world's great cities, with a population of more than half a million souls and rapidly increasing, and yet it had no grounds for public recreation, no pleasant roads for riding and driving, no opportunities for refreshing contact with natural scenery. There are half a dozen cities in the country now whose park area is measured by thousands of acres, and yet in 1851, when Mayor Kingsland, of this city, had been spurred to the point of proposing to devote as much as one hundred and sixty acres of an unpopulated portion of Manhattan Island to public use as a pleasure ground, the project was denounced by many eminent citizens of that time as extravagantly large. The change of popular sentiment between that day and this is certainly very marked, for now not only have large areas been secured in the suburbs to meet the future wants of the growing city, but our Legislature has just passed an enactment compelling the destruction of entire blocks in the most thickly peopled parts of the city in order to make space for gardens and playgrounds.

No one who has looked into the history of public parks in American cities and the development of the public sentiment which brought them into being, will deny that the strongest impulse which the movement received at the outset came from Andrew Jackson Downing. Mr. Downing was born with a strong love of nature, and as his father was a nurseryman he was brought up in a calling that increased his interest in trees and planting. Reared almost in sight of many of the old places on the Hudson which had been planned and planted by Parmentier and others of that older school, he learned while still young that a landscape could be made impressive by the simplest and most natural treatment. As he was to become our first authoritative writer on the art of landscape-gardening, the whole country has occasion to be thankful that he was in this way led to adopt what was then called the English style of gardening, in which, to quote his own words,

"the spirit of nature, though softened and refined by art, always furnished the essential charm, thus distinguishing it from the French or Italian style, where one sees the effects of art slightly assisted by nature." Downing was a man of catholic views, but while he realized the fact that vases and balustrades and studied symmetry might be mingled with foliage enough to make a garden, yet his ideal garden-scene was the primeval paradise, whose pervading beauty was found in the unstudied simplicity of nature. With his natural taste refined by travel and by study, Downing's Treatise on the *Theory and Practice of Landscape-Gardening*, which was published in 1841, became at once the accepted text-book of rural art in this country, and this book, passing through many editions, and his *Rural Essays* and other works, are still classics in this branch of literature. It was his example and precept which inspired such men as Henry Winthrop Sargent, and they in turn kindled the enthusiasm of younger men, so that the best private gardens in America to-day owe what is best in them to his sound teachings.

Downing was a graceful and forcible writer as well as an artist of the highest intelligence, and as he had been already recognized as an authority a timely series of letters which he wrote for *The Horticulturist* on the subject of public parks in 1849 had a marked influence in creating and molding popular sentiment in this direction. These essays, which appeared month after month, and were widely copied by the press, marshaled in a convincing way the arguments which were then fresh and original, although many of them have since become a part of our common knowledge and belief. He began by showing that public parks were needed not only to educate the public taste, but because everybody at some time felt the necessity for this contact with nature. He showed that this communion was not only a delight to people who were as unsophisticated as children, but that the more thoughtful and educated a community became the stronger grew the passion for rural pleasures. When it was argued that the people would not visit parks, even if artistic ones were constructed, he pointed to the large cemeteries to prove how eager all classes were to avail themselves of an opportunity for a visit to anything resembling a park. Mount Auburn, Greenwood and Laurel Hill had been already established for a quarter of a century, and that they had come to be places of resort was certainly not because they afforded opportunity for solemn meditation or for the artistic value of the monuments reared within them. He truly argued that it was because they contained bits of forest-land, hills and dales, copses and glades that they attracted throngs of visitors in cities which possessed no great public gardens, and that if thirty thousand people would visit Laurel Hill in one year many times that number would visit a public park in a city like Philadelphia. He set his argument on the highest plane at the very outset, and, while recognizing the use of parks as helping to furnish air and sunshine, he held that the fostering of the love of rural beauty was quite as important an end, and that such a love of nature helped to civilize and refine national character. Mayor Kingsland's proposed park of a hundred and sixty acres he pronounced altogether too scant, and argued that five hundred acres between Thirty-ninth Street and the Harlem was the smallest space that should be reserved for the wants of the city, since no area less than this could furnish a rural landscape or offer space enough for broad reaches of park-land with a real feeling of the breadth and beauty of green fields and the perfume and freshness of nature. It was argued by some who assumed to represent the laboring classes that the park would be monopolized by those who ride in their carriages, and, on the other hand, some of the wealthy and refined people of the city complained that a park would certainly be usurped by rowdies and low people. It is refreshing now to read Downing's replies to such objections. He stoutly asserted that these social horrors were nothing but phantoms of the imagination; his faith was, as the event has proved, that

rich and poor could breathe the same atmosphere of nature and of art and enjoy the same scenery without any jealousy or any conflict.

The actual work of constructing Central Park was not begun until six years after Downing's untimely death, but it was his stirring appeals that aroused the city to feel its need, and provision to meet it quickly followed. By rare good fortune, too, designers were found, whose artistic temperament and training were akin to his own, so that our first great urban park was planned on such broad lines as he would have approved. The works which followed at once in Brooklyn, Buffalo, Chicago, San Francisco and other cities were beyond question the result of this same inspiration, so that his keen foresight and conscientious devotion to an idea were the most powerful of the agencies which united to initiate the movement which has given to American cities their thousands of acres of park-land during the past thirty-five years. When we think of the health and comfort, the rest and the refreshment, the delight to the eye and the imagination which these smiling landscapes have given and will continue forever to give to all the people, it is not too much to say that Downing takes rank among the greatest benefactors to his country which this century has produced. It is now more than forty years since he met death in trying to rescue others. Is it not time that some memorial of him should be erected in the park which his genius secured for the city? There are too many statues now in Central Park, such as they are, and it may be that a statue is not the most appropriate way of commemorating the work of such a man as Downing. But somewhere in grove or glade it is certainly possible to place a fitting memorial to one whose life was devoted to the cause of rural art. We are glad to know that this thought has occurred to more than one person lately, and that a movement is partially organized to carry it into effect. There can be little doubt that enlightened Americans will delight in an opportunity to keep green the memory of our earliest master in horticulture and landscape-art.

The Chino Valley Experiment Station.

THE large farm station which the University has established in the Chino Valley, Southern California, is situated about equidistant from three important towns, Chino, Ontario and Pomona. It is in a very prosperous region, embracing many varieties of soil, different elevations and exposures, and consequently different climates. Near the mountains the rim of the valley is largely occupied by orchards of citrus fruits. On the Chino side the leading industry is beet-culture for sugar, one of the most famous factories in the United States being located here. The total output of refined sugar last year was 9,471,672 pounds.

The experiment station occupies two pieces of land. The home tract, thirty acres in area, is near the middle of the valley, and irrigation is necessary here to secure the best results with most crops. The other tract, ten acres of moist land requiring drainage, is two miles distant, and represents quite a large extent of country. Though the home tract is more typical of the valley as a whole, some of the best sugar-beets come from the rich, moist bottoms. Both tracts, together with the water-supply needed for the larger, were given by Mr. Richard Gird, owner of the famous Rancho Chino, when the station was established.

The station orchards comprise Olives, Figs, the Citrus fruits and deciduous fruits, besides experimental vineyards of wine and table grapes, including the new Persian varieties recently introduced, and considered of especial value for warm districts. Twenty acres are now occupied by permanent plantations. The orchards and vineyards are well kept, and every tree is distinctly labeled, besides being on the record books. The large orchard book shows in the case of each tree the plat, the row, the number, the name, the source from which stock was obtained, the age when planted, and the date of planting. It then gives the

records of bearing for each successive year—the date of bloom and of ripening, quality of fruit and total yield, with space for memoranda. A more complete record is kept separately for each species of fruit. The charts show every point where soil has been analyzed, or experiments tried, and the results from time to time obtained.

The orchards of various trees in this station will, in two or three years more, when trees now in nursery are set, contain upwards of twelve hundred varieties. Some kinds are represented by but one tree, but others require several specimens so as to make more careful tests, or because they are on somewhat different soils.

The University has already under cultivation at its stations 240 varieties of Apples, including Crabs; 25 varieties of Almonds; 45 varieties of Apricots; 75 varieties of Cherries; 70 varieties of Figs; 20 varieties of Nectarines; 250 varieties of Peaches; 175 varieties of Pears; 120 varieties of Plums and Prunes; 20 varieties of Walnuts and 30 varieties of Citrus fruits, besides Persimmons, Mulberries and many other fruit-bearing trees.

Everybody who has attempted to establish an experimental orchard knows that after the first hundred or so varieties are obtained the task of selection becomes one of increasing difficulty. The plan at the Southern California station is to secure standard varieties for comparison, and promising seedlings from the Pacific coast, the southern states, Europe, Australia, Japan, and other regions with similar climates, discarding or sending to another station those varieties that prove inferior here, unless some other characteristic renders them useful for hybridizing. Georgia, Alabama and other southern states have contributed some of the most valuable seedling Peaches, not only for cultivation, but as parents of new varieties. The Chinese Flat Peaches, so useful in Florida, have never been popular in California. The Chinese Cling type is considered very desirable in some regions. The Chino Valley seems particularly well adapted to the Almond, Prune, Peach, Apricot, Olive and Orange, and less suited to the Cherry, Apple and Pear, although fair results are expected with the latter fruits in certain localities.

A brief synopsis of the work accomplished at this station since its formation will serve to illustrate some of the local advantages. July 14th, 1890, Professor Hilgard chose the site, reporting that the thirty acres consisted of reddish mesa soil and gray gravelly soil, the former predominating. The moist land tract was a dark, rich loam. About the end of November, 1890, the University took charge of the station, a house and barn having been meanwhile built, and water secured through a three-inch cement pipe.

February 19th, 1891, orchard-planting was begun, the land by this time being cleared, graded and plowed. Owing to heavy rains and an unusual overflow from the adjacent wash, or winter channel of one of the numerous creeks, planting was not completed until the middle of April, fully a month later than is desirable. About 800 fruit-trees, representing 365 varieties, were set in orchard form; seventy-five varieties of Grapes were planted in the vineyard; ten named varieties of Date Palms, and many other rare trees were also secured, and a nursery was commenced. The culture plots included the leading cereals, Sorghums, forage-plants, etc.

During the summer of 1891 a circular reservoir of cement, containing 100,000 gallons of water, was constructed on the highest point of the thirty-acre tract. The streets surrounding the land on two sides were graded, and the following winter choice shade-trees were planted around the entire tract. The orchard and vineyard were enlarged and a collection of some twenty species of *Vitis* was added.

During the summer of 1892 a small greenhouse was built and the offices considerably enlarged. The deciduous fruits received no irrigation; the Citrus fruits were watered three times during the summer. Peruvian Cotton, five varieties of true Sugar-cane, Cassava, Tobacco and a large collection of varieties of Sweet Potatoes were grown this year. Some of the Grapevines planted in 1891 bore fruit.

In 1893 further additions were made to orchard and vineyard. The older vineyard bore well, and so did some of the Peaches, Almonds, Cherries, Plums and Apricots. Four varieties of Orange-trees planted in the summer of 1891 bore five or six fruits apiece. Twenty varieties of Sweet Potatoes were grown, and were analyzed at the Central Station. Collections of small fruits were commenced.

In 1894 the fruit crop was large. Nearly all the Olives, Peaches, Oranges, Lemons, Almonds, Plums and Prunes, Apricots, Figs and Cherries yielded more or less liberally. Some of the Apples and Pears also bore to some extent. Small fruits were very abundant. During the winter of 1894-95 an orchard of special fruits on selected stocks was commenced on ten acres of moist land.

Extensive experiments with Sugar Beet culture were carried on each year on a larger scale. In 1894 about five acres were devoted to this crop. Many successive plantings on different soils, using all the leading varieties of seed and analyzing both soil and beets as often as deemed necessary, led to results, considered locally, of prime importance to the beet-sugar industry of the Chino Valley. These experiments are being continued on a still larger scale the present season. A small chemical laboratory has now been fitted up for the foreman, who is competent to make the simpler analyses on the ground.

But a little more than four years has elapsed since the first planting was done at this station. The visitor now sees orchards and vineyards in bearing, a garden of Roses, shrubs and various flowers, a small arboretum of choice ornamental trees, extensive culture-plots, varying from year to year; and, in brief, the materials in readiness for much experimentation. This has been accomplished in four years by the toil of one foreman, who has had one laborer the whole time, and a second man only about nine months in the year. It is a record of which the University may well be proud.

Niles, Calif.

The Saguenay Region.—III.

POTENTILLA TRIDENTATA, a low plant with smooth, evergreen leaves, covered dry rocks where a thin coating of soil gave its woody roots a chance to grow, and still showed some of its white flowers near the end of August. **Potentilla Anserina** crept about in the low, sandy ground at the mouths of streams which entered the bay, and **Ranunculus Cymbalaria**, with its small, round leaves and spreading stems, covered wettish or muddy spots in similar localities. In the moist, grassy land, near the mouth of Mars River, our wild Forget-me-not, **Myosotis laxa**, grew, and some sprays of **M. versicolor**, a low hairy plant, resembling **M. verna**, but with yellow flowers, changing to blue or violet, were taken from waste ground in the streets of Chicontimi, where it had been introduced. Two small annuals of the Figwort family, **Euphrasia officinalis**, Eye-bright, and **Rhinanthus Cristi-galli**, the Yellow Rattle, were common in rocky fields and on grassy slopes, the tiny bluish flowers of the former exceedingly pretty when peeping out from the low grass of lawns and pastures, the latter rather stiff and homely with its conspicuous, inflated pods. From dry rocks at "Cross Point," near the mouth of the Saguenay, were gathered some specimens of a Whitlow Grass, **Draba incana**, var. **arabisans**. Its floral season had passed some time before, but the tufted branches near the root, well provided with small oblanceolate leaves, hoary with stellate hairs, gave interest to it. From the same rocks, near the water's edge, were plucked the handsome flowers of the Beach Pea, **Lathyrus maritimus**, a very common plant along the sandy shores of the Great Lakes. Near by, on wet rocks or by the banks of brooks, grew the Hemlock Parsley, **Conoselinum Canadense**, the tallest stems, with their finely cut compound leaves, making of it an attractive plant.

Marine plants were quite abundant, for the tide sweeps up the Saguenay, rising to more than twenty feet at the head of Ha-ha Bay, rushing into the coves and covering

many of the low-lying rocks, and bringing in brackish water. In the tide-swept mud along the shore were **Tissa marina** and **Plantago maritima**. The latter was very variable in size and appearance, growing also in the crevices of rocks wet by the tide. Here it might be but two or three inches high, with cylindrical leaves, scarcely thicker than a needle, but when growing in the clays the leaves might be half an inch wide and half a foot or more in length. The Sea Milkwort, **Glaux maritima**, grew upon the wet rocks and sands at Tadousac, and close by tide-water, near the mouth of the Saguenay, the Scotch Lorage, **Ligusticum Scoticum**, was found. **Solidago sempervirens** grew in various places by the river. It has thick smooth leaves and showy heads with golden-yellow rays, characteristics which bring it into prominence as it stands on the wet rocks or slopes, usually close to tide-water. **Atriplex hastata** was met with along the river and in waste ground at Chicontimi, for it is weedy in its habits. It is, in consequence, not restricted to marine conditions, but has become an abundant weed in the salt regions of western New York, and is common about the Great Lakes, even spreading away from them along the road-beds of railroads.

The Compositæ were quite well represented. Among the more interesting was **Aster macrophyllus**, in the open woods or along their borders; **A. acuminatus** on the shaded slopes, generally poorly furnished with flowers, the stems sometimes bearing but one or two heads. **A. tardiflorus**, a low plant with pale violet rays, appeared occasionally in the damp soil of shady places. **A. umbellatus** was one of the most common Asteris in the damp thickets or along the streams. **A. Novi-Belgii** grew upon the wet rocks, its medium-sized heads, with rays of bright violet-blue, making it an attractive species. A form of **Erigeron Canadense**, about a foot high, covered with pink or pinkish flowers, made a pretty plant and caused its weediness to be overlooked. A few were seen in the gravelly deposits at the mouth of Mars River. It reminded one of a similar deviation from the normal form of the common Milfoil, occasionally found in the wild state, and which has obtained a place in the flower-garden, where the white flowers have given way to those with rose-colored rays. With its fine sprays of flowers the Butterweed was almost as neat a plant florally, and did not seem a greater variation from the type.

One of the most interesting Golden-rods was **Solidago bicolor**, with its whitish or cream-colored rays, and growing mostly on the rocks. Though generally grayish, with short pubescence, when in the shade of cliffs or under evergreens, it became quite smooth in the variety **concolor** and had very green leaves with a surface almost shining. **S. lanceolata**, when on the rocks, had thick leaves, with somewhat the same shining, evergreen appearance. Sometimes it would be much dwarfed, and but five or six inches high in such situations. Among the Pines on the higher ground and ridges, the mountain species, **S. macrophylla**, was seen. It has a wand-like stem and showy heads, which are large for a Golden-rod. The bright green leaves were not at all remarkable for size, as its name might indicate. **S. uliginosa**, a species with larger leaves, found a congenial place on the wet rocks, though oftener seen in sphagnous swamps. **S. juncea** and a slightly hoary or minutely puberulent form of **S. humilis** were taken from rocks on the banks of the St. Lawrence at Tadousac. The latter strongly reminded one of **S. puberula**. Two of the Hawkweeds, **Hieracium scabrum** and **H. Canadense**, were on the common Pine plains and gravelly banks. **Prenanthes altissima** was a frequent plant by the margins of woods and in rocky ground, with a great variability in the shape of its leaves and in height of its stems. **P. serpentina**, with much thicker and less variable leaves, grew very abundantly in the sandy ground at Tadousac.

Some of the introduced plants proved of interest, especially the weeds with which I was less familiar at home. **Thlaspi arvense**, the Mithridate Mustard, or Penny-cress, was sparingly found at St. Alphonse, its broadly

winged flat pods suggesting a greatly enlarged fruit of the Shepherd's-purse, and quite pretty in their way. The Bugloss, *Lycopsis arvensis*, a small, but very rough, hairy plant, was occasionally seen in the dry fields. In the grain-fields were the Corn Spurry, *Spergula arvensis*, and *Sonchus arvensis*, the large heads of the latter, with glandular bristly involucra and bright golden-yellow rays, being rather handsome. As it sprang up in the Oat-fields, which had apparently been plowed over in the spring, it had all the appearance of an annual, or, at least, of a plant fruiting the first season from the seed. This also seemed evident from an examination of the root, which was not a creeping root-stock, but with the main axis vertical and with smaller branches, as in the roots of the more common Sow Thistles. Of Vetches I noticed *Vicia sativa* and *V. hirsuta* in the Wheat-fields or mixed with the Pea-vines, while along the field-borders and in the fence-rows was the native Vetch, *Neracca*. Though mostly weeds, and somewhat troublesome, the neat pinnate leaves and bright flowers of purple or blue make handsome plants of these Vetches. The little Hop Clover, *Trifolium procumbens*, abounded in the dry fields and meadows. *Euphorbia Peplus* frequently appeared as a weed in waste ground. In such places the Mugwort, *Artemisia vulgaris*, was very common, as well as the widely disseminated *Ranunculus acris*. The Bladder Campion, *Silene cucubalus*, grew up in the field-borders, and when among bushes became very slender and three feet tall sometimes. The flowers generally perfected but five stamens, the five remaining ones attaining but half the usual length, or appearing as short rudimentary stubs at the base of the calyx-tube. The Abbé Provancher, in his *Flore Canadienne*, perhaps alludes to a more extreme case of this barrenness, stating that the flowers are sometimes subdioecious.

Chicago, Ill.

E. J. Hill.

Plant Notes.

Rhododendron Vaseyii.

THE attention of our readers has often been called to the value of this Carolina plant in northern gardens, and on page 377 of the first volume of GARDEN AND FOREST a figure of it was published. Its hardiness has now been satisfactorily demonstrated in the neighborhood of Boston during the past winter, which has been one of the most severe on plants that has been experienced in the last quarter of a century, killing the flower-buds of most varieties of the so-called Ghent Azaleas, in which are mingled the tender Pontic Azalea and some of the American species. So severe have the effects of the winter been that many old plants of the Ghent Azaleas have been killed to the ground; the evergreen Rhododendrons have suffered seriously and the Japanese Retinosporas and other conifers are killed or badly mutilated. Rhododendron Vaseyii, however, is blooming better than ever and the pure pink flowers are delightful. It is not an evergreen species, and, like the Rhodora, to which it is more closely related than to any other American plant, it loses its leaves in the autumn and does not regain them until May, after the flowers begin to fade. Although in its mountain home Rhododendron Vaseyii sometimes grows to the height of eighteen feet, in cultivation it begins to flower when less than a foot high, and as the flowers open with those of the Poets' Narcissus it is suggested that a good combination could be made by planting a mass of this Rhododendron and then filling up the place between the plants with the Poets' Narcissus. The perfect clear pink of the Rhododendron flowers combine perfectly with those of the Narcissus, and both plants enjoy moist and not too well-drained soil.

Our readers will remember that Rhododendron Vaseyii is one of the last of the conspicuous plants discovered in eastern America, and that it was not until 1878 that Mr. George R. Vasey found it near Webster, in Jackson County, North Carolina. Subsequently it was detected in Cashiers'

Valley, in South Carolina, and still later on the slopes of Grandfather Mountain, in North Carolina. Among the plants of its class none surpass it in beauty, hardiness and the ability to flower profusely year after year, and when better known it will, doubtless, become a general favorite.

The Ghent Azaleas are certainly very beautiful, but many of them are not hardy, and those which are able to bear the New England climate often lose their flower-buds in severe winters. The species of eastern America will, therefore, be found more satisfactory for general planting in our severe climate; their flowers cannot boast, it is true, the range of colors that have been obtained in the more delicate hybrids, but the hardiness of the plants compensate for this; and by selection and hybridization between the eastern American species a race may be produced free of the Pontic strain, which has weakened the constitution of the Ghent breed. English raisers of Azaleas have been using of late years the California Rhododendron (*Azalea*) occidentale to cross with the Ghent Azaleas. It is a very beautiful white-flowered species, and some of their new hybrids are very handsome, but Rhododendron occidentale is, unfortunately, tender in our climate, and the crosses from it will not probably be very satisfactory here.

CARAGANA ARBORESCENS.—This Siberian Pea-tree is now in bloom in the parks of this city, and its bright yellow flowers appearing among the light green downy leaves make it really attractive. These flowers are often said to resemble those of the Laburnum, but really the flowers of the Laburnum, as they appear in long graceful racemes in England and other places where the climate suits the tree, are much handsomer. The Laburnum, however, does not thrive in this country except in a few favored locations, while the Caragana, by its perfect hardiness and its adaptability to all sorts of soils, is a plant that we can always depend upon. It sometimes reaches a height of twenty feet and assumes a genuine tree shape; it will bloom when it is only three or four feet high, and it has a special value in that it produces flowers of a color which is comparatively rare at this season. These Pea-trees, for there are a number of species and varieties in cultivation, belong to the Leguminosae, and, with the exception of the Red Buds, they are the earliest of the family to flower.

SANGUINARIA CANADENSIS.—The Blood-root is among the most attractive of our early-flowering plants, and although the petals fall quickly, when growing in a mass, as it is usually found in nature, fresh flowers continue to appear for several days. These are white, star-shaped and solitary, with a yellow centre. The flower-bud comes out of the ground from the thick root-stock with the leaf wrapped snugly about it. As soon as the leaf opens the scape lengthens, so that the flower is lifted well above the kidney-shaped leaves. These continue to expand after the flowers are past and reach considerable size, so that a mass of them is highly ornamental. The plant thrives in a well-drained soil, but it needs moisture, with some shade, and it does best where it can revel in peat and leaf-mold. It is easily cultivated when these conditions are supplied, and, as Mr. Horsford has pointed out, it does better when planted in clumps of at least six to ten roots, perhaps because the broad leaves shade the ground and keep it cool. When growing wild it is oftenest found in fence corners and similar places where the dead leaves are swept together by the wind, no doubt because mulch of this sort is so effective in keeping the soil damp and cool, as well as furnishing the kind of food in which it delights. The plant derives its name from the orange-red juice which exudes from its root-stock, and to some extent from the flower-stem when cut or bruised. The photograph of a little group of these flowers, which is reproduced on page 215, was taken by Miss Edith Eliot, of New Bedford, Massachusetts.

ALYSSUM SAXATILE.—This old plant, which has been cultivated for more than a century, makes a very pleasing display just now. It is an excellent subject for the rock garden, and never shows better than it does when its pros-

trate stems are hanging over stone ledges. In a slightly elevated position it thrives the best, for it resents water about the roots in winter. The flowers are fragrant, of a golden-yellow color, and are borne thickly in panicles at the ends of the stems. It is rather shrubby at the base, and rarely grows more than a foot tall. Although it gives the best results in an elevated position, nevertheless it makes a good border-plant in a sunny place when the soil is well drained. It is easily raised from seed. Seed sown in March make large plants by the fall.

ARTHROPODIUM CIRRHATUM.—This is an interesting and attractive greenhouse herbaceous perennial which flowers at this season. It is a New Zealand Liliaceous plant with partly folded grass-like leaves, some two inches broad and eighteen inches long. These leaves are gracefully curved and radical. The flowers are borne in loose racemes on jointed stems well above the foliage. The flowers individually are pure white, with prominent yellow stamens, about three-quarters of an inch in diameter, and the white petals are well reflexed. They endure for several weeks, and the plant is ornamental either with or without them. It offers no difficulties in cultivation, growing strongly in

established practice for three or four years, but it was not until last year that the application of Bordeaux mixture for the scab fungus was extensively tried by apple-growers. Many of these experiments with the fungicide were remarkably successful, and they have had a noticeable effect upon the operations this spring. Few persons are now spraying orchards with Paris green alone, but they are combining the poison with the fungicide, and thousands of acres of orchards are being treated with this combination.

For the most part these applications are well made, and the growers are willing to repeat them two or three times. Yet I am more and more convinced that still greater thoroughness is the secret of ultimate success. The Bordeaux combination adheres to the twigs and foliage for weeks, and I am sure that one thorough application of it is more efficacious than two or three carelessly made. This has been well illustrated in some experiments which I have just made on a large scale for the destruction of the Canker-worm in an orchard in Orleans County. It is well known to experimenters that this rapacious insect is readily killed with Paris green, and yet the greater part of the most painstaking orchardists of western New York who have had experience with it have failed to completely rout it by spraying. Some persons have even used a mixture of Paris green as strong as one pound to forty gallons of water, with indifferent success. The trouble is that the

Fig. 32.—Blood-root, *Sanguinaria Canadensis*.—See page 214.

sandy loam in a greenhouse temperature. It is increased by seeds, division and offsets.

IRIS KOCHII.—Among the large early-flowering bearded Irises this stands distinct among the many purple kinds now in bloom. The large flowers are of a peculiarly rich dark vinous-purple color, which is very effective and striking. Besides the typical *I. Germanica* there are a number of hybrids in the same section with various shades of purple, but none more effective than this Istrian species.

Cultural Department.

Orchard Notes from Western New York.

NEVER before has there been so much interest in spraying orchards, and in the best parts of the fruit sections of western New York nearly all the fruit-growers will spray their trees. The people have now had sufficient experience in the operation to ask most explicit questions about every detail. In the Apple districts of Wayne, Ontario, Monroe, Orleans and Niagara Counties, it is no longer necessary to exhort the fruit-growers to adopt the practice, for they are already convinced and are now chiefly concerned in perfecting the methods and appliances.

Spraying with Paris green for the Codlin-moth has been an

insect appears suddenly in great numbers and eats voraciously. The treatment which is needed, therefore, is not one of great strength, but one of great thoroughness, so that every portion of the foliage may be coated with the poison. The worms must be killed quickly, before they have eaten far, for five or six of these greedy creatures soon dispatch a leaf. On trees where the worms would average this number to every leaf we were able to destroy them all with two applications of a pound of Paris green to 200 gallons of water, and in some cases even a single spray was sufficient. But this spray was liberal and thorough. On old trees we applied as much as six gallons to each tree, while growers in general were using from one to two gallons of a twice or thrice stronger mixture with poor results.

Another remarkable feature of the present spring in the Apple regions is the great number of orchards which have been plowed up and put under clean culture. The repeated failures of the apple crop in recent years have now thoroughly aroused the growers of western New York. For a time they waited, hoping for productive years, as of old; but the crops did not come, and now an effort is making to bring the crops. I doubt if the experiment of reviving old Apple-orchards by tillage was ever tried on such a gigantic scale as it is now being tried in western New York. In the meantime it is gratifying to know that the rural population is at last ready to accept the teachings of investigators quickly and fully.

Cornell University.

L. H. Bailey.

Hardy Cypripediums.

OUR native Cypripediums, while not rare plants, are yet uncommon in cultivation. Few hardy plants are more interesting, and, judging from the number of common names given to them, the interest is not confined to gardeners. The general name, Lady's Slipper, is a contraction of Our Lady's Slipper—that is, the Blessed Virgin's. *C. pubescens* is also known as Moccasin flower or root, Nervine, Nerve-root, Water Nerve-root, Umbil-root, Noah's Ark, Indian Shoe, Bleeding Heart, American Valerian, Pine Tulip, Money-flower, Slipper-root, Venus' Cup and Venus' Shoe, Yellows. By the Indians it was called the Night Hawk's Shoe (*pishko-ta hápe*.—Dakota), Rabbit's Shoe (*tchukfi i-shulush*.—Choctaw), Whippoorwill's Shoe (*kwikohia-otakwa*.—Onadaga). These names have also been applied to the other species. In addition, the Cherokee Indians know *C. parviflorum* as the Partridge Shoe (*Kkwe ulas ála*), and *C. acaule* is known as Old Goose, and *C. arietinum* means Ram's Head Lady's Slipper.

The Cypripediums are among the popular simples, being a gentle nervous stimulant or antispasmodic, used for the same purposes as Valerian-root, *Valeriana officinalis*. It has been claimed that *C. spectabile* and *C. acaule* have narcotic principles. *C. pubescens* is the only one named as *officinalis*, however. It is not possible to discover the annual consumption of the root within a number of tons. Its use has been decreasing in recent years in competition with English valerian.

As garden-plants Cypripediums are apt to be short-lived unless one can manage to secure the rather difficult conditions of rich moist soil in shade and nutrient in the way of decaying vegetation on which they revel. However, if well-formed crowns are secured in the fall the plants will do well for a while under trying conditions. *C. parviflorum* has grown very well in my garden in heavy soil, with a northern exposure, under the shade of a Pear-tree. Just now *C. pubescens* and *C. spectabile*, sent by Mr. Mann from a Tamarack-swamp in Wisconsin, are as vigorous and sightly as one could wish. It is very probable that sphagnum would prove a very successful medium in which to grow these plants in our gardens, taking care to give an occasional dressing of rotted leaves. They are readily forced by planting in pots or flats, which should be kept in the frames and brought into temperate warmth early in the year.

Aside from the interest in growing these wildlings successfully, they seem to me to be among the plants more thoroughly enjoyed if sought out and discovered in their haunts while they are in flower.

J. N. Gerard.

Some Hardy Perennials.

Fritillarias.—The different species and varieties of *Fritillarias* add much to the attractiveness of the spring garden, and it is a mystery why plants so easily grown are not more common. The stately Crown Imperial, in its many varieties, is most frequently seen, and it is the most conspicuous plant in the genus. When well grown its stout leafy stems attain a height of four feet. Its drooping flowers are nearly as large as Tulip-flowers, and they vary in color from yellow to crimson. The flowers are produced in whorls at the top of the leafy stem, which are surrounded by a crown of foliage. The varieties of this plant are numerous, but there are two forms with variegated foliage. One has silver-striped leaves, and the other has gold-edged leaves. The Crown Imperial is not particular about soil, but does best in a light sandy loam well enriched with manure, and a slightly shaded position suits it well.

Fritillaria Meleagris, the Guinea-hen-flower, is a pretty European species, and it has many showy varieties. It does not grow as large as the above species; the stems only attain the height of one foot. The pendulous flowers are produced singly on the top of the stem, and are checkered with pale and dark purple. The white variety of this plant is very pretty, and well worth growing. *F. obliqua* is a neat and distinct plant from the Caucasus. The stems, which are about a foot high, are clothed with numerous oblique glaucous leaves, and its flowers are brown-purple. *F. ruthenica* is another good dwarf species that is perfectly hardy. Its flowers are brown and yellow, and it is about a foot high, with linear lanceolate leaves.

The dwarf kinds are excellent plants for sunny borders, and when set in small groups they are very pleasing. The bulbs when once established should not be disturbed often, and when they are transplanted at any time they should not be kept out of the ground long, as it weakens the plants. The bulbs of *Fritillarias* should be bought early in the season, August or September, and when once procured there should be no delay in getting them into their permanent positions. Large bulbs

should be planted six or eight inches deep, and the smaller kinds from four to six inches deep. Care should be taken not to put the bulbs where water will settle around them in winter.

Anemones.—A beautiful little plant is *Anemone sylvestris*, with its pure white drooping flowers. When nicely grown it has a neat habit, the three-parted leaves spread out and touch the ground and grow up around the flower-stems in a pleasing manner. When it is in flower the plant measures from twelve to fifteen inches in height. It comes from Siberia and central Europe, and is quite hardy here. A light rich soil in a slightly shaded place seems to suit it. *A. nemorosa*, var. *Robinsonia*, when it once gets the right situation and feels at home, is the most beautiful of the Wind flowers. It must be seen on a bright sunny day with all its flowers open, for, under any other conditions, its full beauty is not displayed. The habit of the plant differs little from that of our native *A. nemorosa*, but its flowers are much larger and of a bright sky-blue. It is a British plant, but grows luxuriantly here, and does well in a light rich soil, and a slightly shaded position prolongs the flowering season.

Orobus vernus.—Plants with pea-shaped flowers are rare at this season, and this fact alone would give a value to this *Orobus*. It is an excellent hardy perennial, and would deserve attention at any season. The plant grows about a foot high, and nearly as soon as the growths are out of the ground the flowers begin to appear. At first they are a mixture of green, red, purple and blue, but when they get a little older they turn almost blue. This is a good border-plant when it has good rich soil.

Saxifraga peltata.—At the edge of a small pond this largest of the Saxifrages is throwing up its vigorous flower-stems. These stems, which rise from a stout, fleshy, creeping root-stock, are from eighteen inches to two feet high and three-fourths of an inch thick at the base. The flowers are in large clusters and rose-colored. At this time, when the plant is in bloom, the leaves are about ten inches high and six inches across. Later on the umbrella-shaped leaves increase in every way until they are about a yard high and as much across, and are very bold and handsome. It is a moisture-loving plant, and requires to be planted near a pond or running stream; in such a place it very soon increases.

Harvard Botanic Garden.

Robert Cameron.

Some Useful Greenhouse Climbers.

Hoya carnosa.—This fine old climber still holds its own against the newer introductions. Few, if any, of its rivals are more pleasing in flower and foliage, and certainly none are more suitable for covering a back wall. The plant requires a fair share of light, and with ordinary care it will make rapid growth and soon form a spreading mass of glossy green leaves. It commences flowering in March or April and blooms profusely for several weeks, while occasional blooms appear during the entire summer. The peculiar texture of its sweet-scented flowers has given it the popular name of Wax plant. They are rather unsuitable for cutting purposes, as they are hard to procure with any length of stem, though shoots four or five feet in length may be cut with several clusters of flowers attached. The plant requires plenty of root room, and, therefore, does best in a bed, which should be freely drained. A compost of turf-loam, well-rotted manure and a little sand suits it well. It requires an abundance of water while in active growth, but should be kept rather dry during the winter months. A trellis of wood-work or wires should be provided for support to which the shoots should be tied until the plant is well established, after which they will cling readily of themselves and require only an occasional trimming to prevent overcrowding. This trimming is best done after the main crop of flowers is past, when the plant will make and ripen the young wood for another season's flowering, the greater part of the flowers being procured from the young wood. Shading is necessary during the summer months, as the leaves are easily scorched in strong sunshine. Fine specimens of the Wax plant are often seen in old country houses, where they have been grown for years in a large pot. They are taken in the house in any warm corner for the winter, and in summer are set on the porch, or under a tree where they will bloom abundantly with no other attention than a watering every day or so.

Lapageria rosea.—This plant and its variety, *alba*, would be more common if they were not so difficult to establish. Many failures undoubtedly occur because the potting compost is too stiff or heavy. Peat soil or leaf-mold should constitute about half, the other half being made up of good turf-loam and a plentiful dash of sharp sand. It is hard to give too much

water while the plants are in active growth, providing the drainage is good. They suffer if allowed to become dry during the warm weather, and even in winter should be kept moderately moist, the amount of water given being regulated according to the atmospheric moisture of the house. The flowers are useful for wreaths and similar purposes. Nowhere do the large waxy, bell-shaped flowers show to better advantage than when drooping from the roof of the greenhouse, for which this plant is admirably adapted. It is of slender growth and light foliage and does not obstruct the light from the plants below.

Stigmaphyllum ciliatum.—This plant is well adapted for a similar purpose, but is of more rapid growth and heavier foliage. It is of comparatively easy culture and thrives well in a light soil. The flowers, which are produced in panicles, are of a bright yellow color and very showy. They are easily damaged by damp, and on this account the plants should not be syringed when in flower.

Habrothamnus elegans.—This is another old-time favorite. It is especially useful for training to a pillar from which the graceful drooping panicles of bright carmine flowers are displayed to the best advantage. It can be had in bloom during the winter months if it is well cut in about the end of September. There need be no fear of cutting it in hard, as it starts very readily and may be pruned back as close as a grapevine.

William Scott.

Tarrytown, N. Y.

Cyperus alternifolius.—For decorative purposes this is an extremely useful plant, and for growing in Wardian cases, aquaria or positions where it can have plenty of moisture and not too much sunshine it is unexcelled. Planted in the open ground it makes a very handsome appearance, and it succeeds in either the full sun or a heavily shaded situation. It succeeds best where slightly shaded, and last year grew four to five feet high and three feet in diameter. Those who have some old, rather sickly-looking specimens in pots should plant them out, and they will be surprised to note a fine tropical appearance they will have ere the season is over. The variegated form, *C. alternifolius variegatus*, grows less vigorously with us than the green form, but makes a very pretty plant. As young plants are so easily raised from seed and otherwise, it is not advisable to dig up any plants in the fall; they are sure to lose a large part of their foliage after lifting.

W. N. Craig.

Native Violets.—Under cultivation these plants make a rather pretty display of flowers and foliage. Some of them, however, are apt to become troublesome weeds if planted where the hoe cannot be used freely. The principal offender in this line is *Viola cucullata*, which goes on producing short-stemmed apetalous flowers all through the summer, and these flowers are very abundant seed-producers. *V. blanda* is a good species with white flowers and lots of them; it is about six inches high. *V. Canadensis* is a beautiful plant, with leafy stems, and grows over a foot high; it has also white flowers, tinged with violet. *V. pedata* has several forms, every one of which is beautiful. *V. pubescens* has small yellow flowers and very handsome foliage. *V. sagittata* has very variable foliage and pale purple flowers; in masses this looks well. These Violets seem to prefer a heavy loam with the addition of some vegetable mold. *V. pedata*, in its varied forms, usually grows on hard-baked sandy soil, or gravelly soil, and in such situations flowers sparingly all summer long if there are abundant rains, but usually the plants show best in May and late September.

Correspondence.

The Hardiness of *Pinus palustris*.

To the Editor of GARDEN AND FOREST:

Sir,—The note on the hardiness of the Cherokee Rose in a recent number of GARDEN AND FOREST leads me to ask what has been done in the way of testing the hardiness of the *Pinus palustris*? Two years ago we procured a dozen small plants of this species from a point near its northern limit in North Carolina. One only survived the transportation, but this one has lived through the past two winters here with no protection. Even the severe one just past has not materially hurt it. The uppermost leaves are brown and dead, but the lower ones are green. Further than this it is now making a vigorous growth from the crown. The plant is only about fifteen inches high, and it was under the snow part of the time, but there were terms of very severe weather when it was entirely uncovered.

Germantown, Pa.

Joseph Meehan.

[The condition of the plant of this Pine, which has been

growing for many years in the grounds of the Department of Agriculture in Washington, shows that, while it can be kept alive there, it has no ornamental or economic value much beyond the limits of its natural range.—ED.]

Notes from Wellesley.

To the Editor of GARDEN AND FOREST:

Sir,—Mr. H. H. Hunnewell's grounds are open to the public and they are visited by thousands of plant-lovers every season. The superb collection of rare and beautiful conifers and splendid specimens of rare trees and shrubs from all parts of the world are the main attraction to some of the visitors, while others come to see Lake Waban as it appears when looking over the Italian garden of trimmed trees, the finest in the United States. The exhibition of Rhododendrons and Azaleas in June is a special treat to many persons. Mr. Hunnewell has a magnificent collection of Rhododendrons. It may be a question whether the more tender kinds, in which Asiatic blood predominates, will ever be really hardy here. Mr. Hunnewell has, by extreme care in regard to suitable location, and attention to watering during dry weather, succeeded in retaining some of the tender ones in excellent health. Years ago crimson shades were rare, now there are several good varieties of this color.

During the late summer the English flower-garden proves a great attraction. It is a flower picture, a mass of color, effectively arranged in one part of the garden shut in by a rectangular evergreen hedge. The Water-lily tank, heated by hot-water pipes, and containing such tender kinds as *Nymphaea Devoniensis*, *N. Zanzibarensis* and *N. stellata*, as well as some of the handsomer of the hardier kinds, notably *N. chromatella*, has many admirers. A special bed of Japanese Iris is provided with water-pipes, laid so that it can be overflowed during the blooming season—an essential condition to the proper cultivation of these plants. A canopy is spread over them to protect the delicate and many-hued flowers from the scorching rays of the sun.

The conservatory is considered private, but no one is ever refused permission to view the splendid collection of Orchids always on exhibition there. Mr. Hunnewell's Orchids are selected mainly for spring and summer effect. There is just now an immense basket—crate, one might call it—of *Cattleya Skinneri*, and another of its charming white-eyed variety, *oculata*. The brilliant violet-purple of these flowers is very effective. With its fragrant, lemon-yellow, pendent flowers, *C. citrina* is here exceptionally well grown. *Laelia cinnabarinus* and *Ada aurantiaca* give the touch of orange-scarlet needed. *Dendrobium nobile*, in many fine forms, and *D. Wardianum* are indispensable here, as elsewhere. Other Dendrobiums in flower are *D. fimbriatum*, orange-yellow, with dark brown, almost maroon, eye, and fringed lip; *D. Brymerianum*, clear yellow, with a still more fringed lip, and *D. thyrsiflorum*. These add variety and beauty to an attractive group. *Schomburgkia Tibicanis* is a rare and most interesting Orchid, very seldom seen. The plant now in flower bloomed two years ago for the first time in this country. It is a somewhat coarse grower, producing but few flowers in proportion to the size of the plant. They are pink and white and finely penciled.

In the annex to the conservatory, which is open to the public, there is a fine display of spring-flowering plants. It is interesting to note how effective such old plants as *Antirrhinums* are for grouping. There are some finely selected kinds, one of wine-purple being very showy. Another effective striped one, Mr. Harris says, he used to know many years ago as *Caryophylloides*. Azaleas are here used to help the display, although there is a special exhibit of these plants in pots plunged to the rim in a tent in another part of the grounds. *A. orbicularis* is a variety especially worthy of note; it is a Japanese species, and very nearly hardy. The flowers are small, red and white striped, but produced in immense numbers. This species is being used largely in England for forcing. It suffers in comparison with a well-grown plant of tenderer, larger-flowered kinds, but its hardiness makes it much easier to handle, for which reason it is especially well suited for florists' use. A fine standard *Wistaria Sinensis*, Lilies and foliage-plants make grouping for the background, while in front there is a blaze of Pelargoniums such as one seldom sees. Among the best Zonal kinds are Clyde, vermillion-red; Fiery Cross, intense crimson; Belle Poitevine, salmon-pink, and the White Nemesis. Show Pelargoniums are in the majority. The collection contains some extra good varieties. Duchess of Albany is a fine dark-flowered sort; Duchess of Teck, large, white, faintly tinted pink, chaste and beautiful; Albino, white, with a light purple standard; Kingston Beauty, with a deep purple stand-

ard; Lizzie Cannell, the handsomest of all dark ones, with edges white and crimped; Madame Thibaut, another crimped kind, delicately blotched and penciled with rose and white, with crimped petals, and the handsomest of its color; Beacon, one of the showiest—its standard petals are very deeply blotched; Ophelia, a rosy purple, and very distinct, the most striking one of the group. The old Pelargonium Rollissoni must have a word. It is a distinct-looking species, with crimped, woolly and odorous foliage and a multitude of handsome umbellate corymbs of small rosy purple flowers. Show Pelargoniums, when out of bloom, should be ripened well by withholding water to some extent. In autumn Mr. Harris stores his plants in a cool light place where they are kept dry. In midwinter they should be pruned into shape, potted and started into a slow but substantial growth for spring-flowering. The same plants may be submitted to this treatment for several years.

Wellesley, Mass.

T. D. Hatfield.

Lewisia rediviva.

To the Editor of GARDEN AND FOREST:

Sir,—I have just returned from a visit to the experiment station near Paso Robles, where I was interested at finding a small colony of the beautiful Lewisia rediviva. It grows on the high valley land or rolling plain, about two miles east of the Salinas River, at an elevation of eight or nine hundred feet above the sea. The soil is a hard clay and rather sterile, and the plant has not been seen anywhere else in that region. I am not aware that the Lewisia has before been reported south of Monte Diablo in the valleys of California, but I may be mistaken in this, as I am not familiar with its literature, and, indeed, took the plant to Professor Greene for identification. It interested the Botanical Department of the University exceedingly, as it is really a plant belonging to the mountains and to colder districts. Professor Brewer found it on the summit of Monte Diablo, and it extends northward to British Columbia, and east to Montana, Utah and Arizona.

A number of people in Paso Robles who are fond of gardening have moved some hundreds of Lewisia-plants, while in full bloom, and set them out to form edgings. The Lewisia maintains its reputation of being exceedingly tenacious of life, and the large fusiform roots have gone on growing under a hot sun without seeming to suffer in any manner. I saw plants which bore twelve or fifteen large pale pink flowers apiece, and they form a very attractive border at this season. The small colony alluded to is already decimated for the use of such gardens, but the plant grows readily from seed, and is so hardy a perennial that the settlement, though only a few hundred feet across, will hardly be destroyed.

Charles H. Shinn.

Taxation for Municipal Improvements.

To the Editor of GARDEN AND FOREST:

Sir,—Your editorial of April 10th, on the proposed new system of parks for Essex County, alludes to a method of paying for such improvements which deserves more attention and stricter observance. You say "the valuations of property facing the new parks and parkways will be sure to advance sufficiently to more than pay for the improvement." Of course they will, and little reflection is needed to show that here is the natural fund which ought to be taken for every such improvement. That it is ample the history of all improvement abundantly testifies. But is it so taken? Consider what valuation increases with improvements of this kind. If I own a plot of unimproved property facing the park, valued at, say, \$5,000, and my neighbor has a similar plot with \$5,000 worth of improvements on it, it is manifest that, while he will have twice the amount of taxes to pay that I have, his property has increased no more in value than mine. His dwelling, fences, drains, etc., are not one whit more valuable because of the proximity of the park, but they are assessed as if they had an added value. Thus, even on the assumption that real estate is assessed at its true value, an inequality and injustice arises, which is added to by the fact that unimproved real estate is notoriously undervalued for purposes of taxation. Does not this go to show that in levying taxes for public parks and other such desirable improvements, the increased value of the land ought to be the basis of taxation, and improvements exempted? Any other system is, practically, a fine on the men who put their land to use. Your recommendations are in the line of sound public policy. You should go further and declare against a system of taxation which unduly burdens one class of property-owners for the benefit of another.

New York.

Luther G. Sand.

[So complicated a problem as the adjustment of taxes

for municipal improvements can hardly be settled offhand by looking at it from a single point of view. No doubt, the property which faces Central Park has increased in value since the park was planned by an amount equal to the original cost of the land condemned for the park. But, of course, these property-owners were not the only ones whose land was enhanced in value by the park. In the case of Essex County, the entire population voted for the parks. These will minister to the health and pleasure of all the people, and lands belonging to many of them will rise in value, even when it does not lie directly along the boundary of any new park. Almost every community has its own way of doing things, which depends partly on law, partly on precedent, and partly on tradition. A few years ago a wide parkway was built in a New Jersey city, which greatly increased the value of that portion of the city it traversed. All the land which was taken was valued by commissioners, and the owners of this land were paid what was considered its full value. In many cases, where a narrow margin was taken from a lot, it was naturally supposed that the remainder would be worth more when the road was built than the entire lot was originally; but the courts would not allow any deduction from the assessed damages to the land on account of this probable betterment, as it was held that no one knew how much the increased value would be, and it was unjust to tax values which only existed in the future.

As to the point of taxing the land only and not the improvements on the land, it may be said that in most cities where new streets are opened or sewers built taxes are levied by the front foot, without any regard to the value of the dwellings on the property. It may be worth while to note here that, in Baltimore, parks are paid for by taxing the gross receipts of street railways. From an article in *The Municipality and County* it appears that the greater proportion of the cities in the United States do not assess adjacent or abutting property for park purposes. Boston has an odd system of assessing lands about parks within distances varying from two hundred to six hundred feet. In Brooklyn, Prospect Park was made a charge against twelve wards, which composed the old city. Kansas City has a system of submitting to a jury the determination of what assessments against property adjacent to parks are equitable. St. Paul assesses sixty per cent. against adjacent property, the distances from the parks wherein such assessments are made depending on circumstances. In Denver there is an attempt to divide the city into park districts, each one of which shall be assessed for its own public grounds. Altogether, it looks improbable that any uniform system of levying taxes for park improvements can be expected in this country—for some time, at least.—ED.]

Recent Publications.

How to Know the Wild Flowers. By Mrs. William Starr Dana. Illustrated by Marion Satterlee. Revised and enlarged edition. Charles Scribner & Sons.

The popularity of Mrs. Dana's book is proved by the fact that the demand for it has justified an edition which contains fifty per cent. more plates than the old one, so that in this volume a hundred and sixty-four of our wild flowers are figured, and new descriptions of flowers have been added until nearly five hundred flowers are now described. Of course, the disadvantages of a book like this for reference are evident. When a comparatively small number of flowers are selected for identification, among the great number of those omitted there are sure to be many about which the learner will find himself hungry for information. Plants so common as to be generally recognized, very rare plants and those with inconspicuous flowers, are among the classes that are rejected, but all these phrases are comparative. The well-known flowers of one locality may not be familiar in another, and the novice is quite likely at the outset to come upon a flower that has

been omitted as rare, although, of course, he cannot know this. In completeness the book is much inferior to such a manual as Gray's *Field, Forest and Garden Botany*, which includes all the ordinary cultivated plants as well as most of our native ones. If Mrs. Dana's book has any advantage over an ordinary manual of botany in enabling readers to identify wild flowers, this comes from the fact that in it the flowers are classified according to their colors; that is, rather more than a hundred pages are given to plants with white flowers, then seventy-five to those with yellow flowers, sixty to pink flowers, twenty to red flowers, sixty to blue and purple flowers and about a score more to flowers which are classified as miscellaneous. The flowers are arranged something in the order of their opening; that is, the earliest ones of each color are described first. Thus, when the student comes across a red flower in mid-summer he has only to look in the list of that color among the flowers that bloom at that season, and if he finds the picture of it and the description he is made happy; if he misses them he wishes for better luck next time. One would hardly expect to make any great advance in knowledge by following this go-as-you-please plan, but we are assured that many people have carried this book into the country for a summer and have really discovered the names of a good many plants. Let us hope that many of these may be stimulated into something like a systematic observation of the vegetable life about them. If the book helps in any degree to encourage habits of observation, or if it leads to an unaffected admiration for the beauty of flowers and shrubs and trees it will be worth many times what it costs to any reader.

China Aster. Bulletin 90: Horticultural Department of Cornell University Experiment Station.

This compact little monograph is something of a novelty in the way of information from one of our agricultural experiment stations. In some prefatory remarks Professor Bailey discourages the habit of setting formal flower-beds in the midst of a lawn, because the flowers destroy the freedom and breadth of the lawn by cutting it into patches and by introducing brilliant colors and an appearance of activity and fidget where everything should be subdued, quiet and reposed. At the same time a broad stretch of greensward about the bed is the worst possible setting if the flowers are to be seen to the best advantage. Professor Bailey advises having flowers in lavish supply, but in small places he would plant them as borders along a rear walk or against a building. He might have added that there were certain perennials, and even annuals, that can be sparingly planted among the shrubs that border a lawn, although a long, highly colored edging of flowers as the boundary of a lawn may do almost as much to disquiet it as a mass of Coleus set well within it. He might have added, too, that in large places flowers never look more beautiful than when hedged within some formal enclosure where the gardener can gratify his taste for geometry and have the great bulk of his flowering annuals and perennials massed, not only so that they can be more conveniently cared for, but so that they can be arranged to produce brilliant effects without distracting attention from scenery of a more placid character.

On account of their easy culture, freedom of bloom and variety of form and color, these China Aster are among the very best of annuals for popular use, and they have the advantage of being at their best in the late season when the greater part of the perennials are spent and they carry a profusion of bloom until winter sets in.

After a brief history of the evolution of the China Aster from the species *Callistephus hortensis*, or, as Professor Bailey prefers to call it, *Callistemma hortense*, the different classes are described with considerable detail. No effort at an exhaustive classification is attempted, for this is plainly impracticable. Vilmorin divides the varieties into the pyramidal growers and the non-pyramidal, but Professor Bailey suggests as a serviceable scheme a separation into two sections: those in which the florets are open or flat, and those in all but two or three of the outer rows of florets are tubular or quilled.

THE FLAT-RAYED SECTION.—This section may be divided into two classes: (1) Those with ball-shaped flowers, and (2) those with flat or recurved flowers. In the first class are included Truffaut's Paeony-flowered Asters, one of the oldest and best

of the types, moderately tall and vigorous plants, somewhat pyramidal in habit, with small globular and nodding flowers in many colors. La Superbe is one of the best strains of this type. Semple's strain also belongs to the Globe class, so does the Jewell, a strain of rather dwarfer habit than the Semple and flowers less incurved than the Truffaut strain, with short petals and compact symmetrical heads. Triumph is another dwarf Globe-flowered Aster, but it does not seem to have been well fixed in habit as some of the flowers are Chrysanthemum-shaped.

The second or reflexed class of this section includes the so-called Chrysanthemum-flowered strain, the plants having various habits and various merits, and very useful in many colors. The Washington Aster is an offshoot from this strain, and so is the more refined Mignon, with plants of medium height, flowers more regular in shape than the Victorias, which are free-blooming and both tall and dwarf. The Emperor, in various colors, is a tall-growing, late-flowering strain; the plants branch sparingly and carry from three to five large Chrysanthemum-shaped flowers. Queen of the Market, and the varieties of this type called Queen of Spring and Queen of the Earliest, will bloom in August when the seed is sown out-of-doors. They have a free, spreading habit, with long stems, which makes them useful for cutting. The Candelabra group is somewhat like this, but later. The Crown or Cocardeau strain is medium or semi-dwarf, flowering early and abundantly. The centre of the flower is white, surrounded by a fringe of various-colored rays, and the central florets are somewhat tubular, so as to suggest the quilled section, with which they are connected. The Comet is, perhaps, the best of this class, if not the best of all China Asters, with its loose open flowers and long strap-shaped rays. Its color was not quite satisfactory at first, since the pink-tinted florets faded out into a dingy white, but the rose-colored and blue-flowered kinds, which appeared later, were improvements, and the clear white one introduced in 1892 by Vilmorin is altogether satisfactory. Occasionally these Comet Asters sport into an inferior form with a loose border and an open centre. They are not so useful for cut flowers as some of the larger-stemmed and rounder-flowered types. Finally, there is the Imbricated type, sometimes known as Imbricated Pompon, which is intermediate between the flat-rayed and quilled section. The rays are approximately alike, short and rather concave, springing from a tubular base. The heads are medium or small in size, but close and uniform in shape. The plants are sometimes dwarf and sometimes tall, but the habit is always compact, and it is a distinct and desirable strain.

THE TUBULAR OR QUILLED SECTION.—This section is divided into (1) the Button-quilled and (2) the Long-quilled or Needle Asters. The first division, with inner florets short and outer ones longer and flat, is represented by the German quilled in many colors, sometimes with drooping flowers, but mostly with tall and branching growth on long stiff stems. Dwarf Bouquet also comes in many colors. This strain grows only six or eight inches high, with a terminal cluster of small dense heads, with the centre florets short and tubular and a thin fringe of flattish rays. These are good for borders for formal effects. Shakespeare is much like them, but the flowers are most distinctly quilled. The second division of this section, with all the florets elongated and quilled, is represented by the Victoria Needle type, which has no rays whatever, but all the range and brilliancy of coloring of the Victoria type and long quill-like florets. Lilliput is a late and pretty strain in many colors, with small flowers and slender compact quills and tall plants.

The bulletin concludes with a list of 250 varieties offered by American seedsmen this year, the trade names being given without any attempt to determine the synonyms. Very few cultural directions are given, because few are needed. Seeds can be sown indoors or in a frame as early as the middle of April in this latitude if plants are to be grown in pots as specimens for exhibition, but where they are to be grown in borders it is quite as well to sow the seed where the plants are to grow. Last year the seeds of fifty varieties were sown at the Cornell gardens on the 4th of June, in which, notwithstanding the prolonged drought, every variety gave a profuse bloom throughout September and October. Few insects prey upon these plants. Their most serious difficulty is the rust which attacks the underside of the leaf and raises an orange-colored pustule. Timely spraying with ammoniacal carbonate of copper will keep this disease in check. A nozzle should be used which can throw the spray upward so as to strike the underside of the leaf. The first application should be made before the fungus appears, and it should be repeated every week or ten days.

Notes.

Some of the florists' windows are now decorated with sprays of Purple Beech and Laburnum. The dark wine color and soft texture of the young Beech-leaves, the light green of the trifoliate leaves of the Laburnum, and the rich pure yellow of its long pendent racemes make a very pleasing combination.

A male plant of *Nepenthes bicalcarata* is now in flower at the Botanic Garden in Washington. In *The Gardeners' Chronicle*, last year, it was reported that the same thing had happened somewhere in England, and the flowers were arranged in the form of an umbel. The specimen in Washington shows a fascinated growth at the base of the spike, the remaining part being similar to the inflorescence of other *Nepenthes*.

A Washington correspondent writes of a specimen of *Acer insigne*, on a grassy slope facing to the west; it is thirty years old, only twenty feet high, and is a beautiful small tree with large handsome palmate leaves, which, during even the hottest summers, preserve their green color, owing, perhaps, to their leathery texture. This tree is a native of Persia, and commends itself to those who are looking for lawn-trees which will not attain a large size very quickly.

The rooms of the New York Flower Mission, at 104 East Twentieth Street, were opened last Thursday for the reception of flowers, fruit and delicacies for the sick. Fresh flowers with long stems, and carefully packed for transportation, may be sent on Mondays and Thursdays throughout the summer season. Packages not exceeding twenty pounds' weight are carried free of charge by the express companies, as we have explained in former years when noticing this interesting charity.

In a late report made to the Minnesota Horticultural Society, Mr. R. Knapheide, of St. Paul, recommended that the game wardens of the state be empowered to protect wild fruits, which he declares are in quite as great danger of extinction there as the wild game is. He stated that in order to secure grapes, for example, reckless pickers cut the vines off and tore down the entire plant, so that if the practice continues many kinds of wild grapes and other fruits will be totally annihilated in a few years.

Professor Foster, the well-known authority on Irises, has raised a hybrid from seed out of *I. paradoxa*, fertilized by I. Korolkowi, the seed parent belonging to the *Oncocyclus* section, and the pollen parent to the *Regelia* section. The flowers are described as very beautiful in *The Gardeners' Chronicle*, the prevailing tint of the falls being a rich brownish purple, almost black, with purple veins on a translucent pale violet ground, while the standards are thinner, with radiating veins on a violet ground, and, altogether, it seems to be an interesting addition to the class of bearded Irises.

Large plants of tender and crisp-looking Romaine lettuce, started under glass and grown out-of-doors on Long Island, now sell for ten cents each. Mushrooms, which cost \$1.50 a pound during the recent period of cold weather, when their growth was checked, are quite plentiful since the warm days of last week, and bring seventy-five cents a pound. Florida tomatoes cost thirty cents a pound, and the more solid product of greenhouses, fifty cents. Of southern vegetables alone very nearly 100,000 packages were unloaded on the railroad and steamship docks of Jersey City and New York during last week.

The current number of *The Garden* contains a colored plate of *Acidanthera bicolor*, an Abyssinian plant of the Iris family, which ought to be more generally known. As long ago as 1888 we published a figure of this plant by Mr. Faxon, a reproduction of a photograph, showing its appearance when several of the bulbs were planted and grown in a tub, and some interesting details as to its cultivation by Mr. Endicott. The plant is nearly allied to *Gladiolus*, and can be treated like tender species of that genus, although it likes a stiffer soil. The plants that were grown in a tub flowered in October after frost had destroyed the out-of-door garden, and at this season their fragrant and pendulous flowers of creamy white, with chocolate-brown blotches, are very effective for decorating conservatories and living-rooms. When the bulbs are planted early the plants will flower in a border in late summer, but the flowering-time can be easily retarded by planting the bulbs late.

Mr. George H. Englehart, well known as an expert in raising Narcissi, writes to *The Gardeners' Chronicle* that the plant known as *Narcissus triandrus pulchellus* is really a natural hybrid between *N. triandrus* and *N. jonquilla*. The flower of this plant appeared to Mr. Englehart to have a perceptible Jonquil scent and it was sterile, and from this and other reasons he

inferred that it was a hybrid, and, therefore, some ten years ago he began to fertilize *N. triandrus* with pollen from the Jonquil. The seedlings, however, all died before flowering, until this year some have bloomed, and the artificially bred flowers seem to have all the characters of *N. triandrus pulchellus*, with the corona whiter than the perianth and the true Jonquil scent; the leaf-character and all the other features of the variety *pulchellus* are also present. Mr. Baker, in commenting on this specimen, seems to endorse the view of Mr. Englehart, that the plant we have known as a variety of *N. triandrus* is probably a hybrid between that plant and some of the Spanish or Portuguese forms of *N. jonquilla*.

Experiments on a considerable scale were made last year in Orange County, Florida, in cultivating Castor-beans as a commercial crop. The planting was deferred until May, so that the plants had only begun to ripen seed in quantity when the frost came and destroyed them. About 350 bushels of beans were gathered in two cuttings, and the experimenter has reason to believe that if he had planted in February a longer season and greater growth would have given a thousand bushels more before the cold killed the plants, since there were from three to five heads on each stalk which were too green to be of any value when the frost came. Of course, last season was specially unfavorable, and for ten years past Castor-oil plants have lived through the winter and begun to form new heads and ripen seeds early in spring, and it is thought that in the so-called Orange belt plants will go through the winter, as a rule, and bear seed for ten or twelve months. It often occurs that plants live five or six winters, and become real trees before there is frost enough to kill them. The experimenter does not seem to be disheartened, and the tract has been replanted with beans for this year.

Nearly 50,000 crates of strawberries reached this city during last week from North Carolina, the eastern shore of Virginia, Maryland and Delaware. The heaviest supply came on Wednesday, and 15,500 crates were put on the market. Until the latter part of the week, when heavy rains caused the berries to come wet and sandy, they arrived firm and well ripened, though large berries of choice or extra quality have been scarce. Prices at retail range from ten to thirty cents a quart box. The first blackberries of the season seen here, from Georgia, are small and seedy and sell for fifteen cents a quart, and green gooseberries, from Maryland, bring the same moderate price. The only pears now found in the markets are P. Barrys, from California. This variety is successfully carried over in cold storage until nearly midsummer. They are now at their best, the white juicy flesh having a sweet, slightly vinous flavor; they cost \$1.25 to \$1.50 a dozen. Newtown Pippins, the last of the season, cost fifty to seventy-five cents a dozen, and the same price is asked for the few remaining Northern Spies, while Roxbury and Golden Russets bring thirty to fifty cents, and the few choice Baldwins command fancy prices. New California apricots, in five-pound boxes, not fully mature and far from luscious, bring \$1.75, and Black Tartarian cherries cost twenty-five to forty cents a pound. Florida garden-grown pineapples of the largest size, from the keys, bring \$1.50 each. Jamaica limes, small and green, in which state they are preferred for use in fancy drinks, are offered at twenty-five cents a dozen. The sales of fresh tamarinds, from the West Indies, have greatly increased this year. Besides the general cooling qualities for which the pulp covering the seeds is popularly recommended, the fruit is credited with curative action in some forms of sore throat. Their grateful sourness is due to citric and other vegetable acids. Mangoes, from the same islands, sell at the rate of \$1.50 a dozen. Their aromatic fragrance when fully ripe is to most persons a higher recommendation than their stringy and rather insipid flesh, as we get them, but probably very little fruit of choice varieties ever reaches northern markets. The large supply of bananas, with the abundance of other fruits, has caused a drop in the extreme prices of a fortnight ago, and while a few red bananas of choice quality and large size bring seventy-five a dozen in the high-class fruit-stores, good yellow fruit costs only from fifteen to twenty-five cents a dozen. The last Almeria grapes sell for fifty cents a pound, and selected clusters of Black Hamburgs, from Rhode Island hot-houses, command from \$2.00 to \$3.00 a pound. Some idea of the immense quantity of fruit handled in New York city may be had from the wholesale auction sales of one day last week, when 25,000 boxes of lemons were bought by retail dealers, besides 15,500 boxes of Mediterranean oranges, 400 barrels of Jamaica oranges, four car-loads of California oranges, 55,500 bunches of bananas, 8,000 dozens of Bahama pineapples and 600 crates of the same fruit from Cuba.

Street-trees.

ONE can hardly think of a tree planted in the border of a city street without some feeling of pity. The air in which its leaves grow is polluted with dust and smoke, which impede their healthful action, and the soil in which it stands is often sterile, usually paved over, so as to prevent sufficient moisture from getting to its roots, and this aridity is intensified by sewers which hurry the water away as quickly as possible. In the majority of cases no attempt is made to protect it from horses which gnaw its bark, or insects which devour its foliage, and even if the tree survives these hardships it will be mutilated by telegraph linemen or amateur surgeons who will lop off its limbs, and thus invite the attacks of various fungi which will soon carry decay to its heart. Of course, the very hardships to which a street-tree is subjected ought to suggest the greatest care in selecting promising individuals of the species which have proved the most able to endure uncongenial surroundings, which means that only carefully grown nursery-trees of the best form and habit should be planted in the most approved manner in the richest soil that can be secured. But, in spite of all that has been written on the subject, we rarely find that the original work of selecting and planting has been done in a way that is anything like satisfactory.

These things have been said over and over again, so that we feel like making an apology to readers for once more repeating such elementary truths. But what we have seen within a few days past gives evidence that instructions can hardly be given too frequently or too fully. Through a neighboring city and its suburbs for a distance of more than a dozen miles a macadamized pleasure-drive has lately been constructed. Advertisements for proposals to plant the borders of this road with Maples or Poplars were made, and the contract was let to the lowest bidder, who agreed to furnish trees from ten to twelve feet high, to dig circular holes three feet in circumference and two and a half deep, to fill these holes with good loam and plant the trees properly in this fertile soil for eighty-five cents a tree. Of course, it is not possible to buy good trees and plant them properly for that sum. As a matter of history, the trees planted for the city were of the required height and trunk

diameter. A band of Italians dug holes of full contract dimensions, and then, in most cases, enough good soil to honestly fill them was dumped beside them. The trees were then distributed, one being laid by each hole, and it usually remained lying and drying in the sun for several hours, often for a whole day. These trees were mostly Cottonwoods and White Maple, both of which will endure a good deal of hard usage without dying outright. They were generally bare poles with two or three large prong-like roots a few inches long, and no small roots whatever. They were set up in the mold, and this was trodden firmly about them, but they were left without any stakes or guards. Where the holes were made in the hard pan the first heavy rain saturated the soil in the tight basin, and it became in many cases as soft as porridge, so that the slightest touch would tilt over the trees, and, although they have only been planted a month, a large per cent. of them lean more or less from the perpendicular. Most of them are dead at the top, and are putting out a few leaves along the trunk and larger branches. If the season is not too dry many of them will survive—that is, they will not die outright, but will linger out a sickly existence. Of course, there is no hope that any considerable portion of them will ever develop into noble and uniform specimens befitting the stately character of this avenue.

The utterly disreputable character of this work from the very beginning is emphasized by half a dozen trees along this same boulevard, where the owner of the land received permission to do his own planting. He made excavations six feet square and three feet deep, and filled them in with good soil in the early autumn, heaping up this soil to allow for its settling. After a winter of freezing and thawing, this soil had become firm and compact. Norway Maples, with well-formed heads, good roots and uniform size, were bought from a reputable nursery and properly planted the next spring. They were surrounded with a wire netting, and they have now passed through one trying summer and winter. This year they are making a vigorous growth, and stand as an object-lesson to show what the street might have been if intelligent care had been bestowed in making and carrying out the original contract. It is never worth while to plant street-trees at all unless they are planted in this way. The first essential quality of a good street-tree is the beauty of health and vigor. It is better to have no trees at all than to have those which are doomed to disease and premature death.

Of course, in formal planting like this only one variety should be used. The beauty of a country roadside is enhanced by the diversity of its growth, where constant change of form and color gives ever-renewed pleasure to the wayfarer. But when trees stand like a row of columns between parallel lines of buildings, the true formal and architectural effect can only be secured by continued repetition. It is this uniformity which makes an avenue of American Elms so effective. It is not the beauty of a single tree which causes this charm, but it is the multiplied effect of a thousand units which combine to make this a long colonnade supporting its Gothic roof. Of course, the American Elm is not the only tree which can be used to advantage, for in a different way an avenue of stately Tulip-trees may be quite as beautiful, while a row of Pin Oaks would have an effect distinctly their own, but unexcelled in grace. If all these trees were mingled together the effect would be dissipated and lost, as there would be no continuous line extending through the whole vista to give it unity of expression and consistency of purpose. This incongruity would be seen at once, and it would be exaggerated with each succeeding year, not only as the trees vary in rapidity of growth, but their peculiarities of form and size and expression would grow more striking and more contradictory every year.

The sum of the matter is that every city should plant its own trees as much as it should pave its own streets. The work, of course, should be superintended by experts, who, to do the best work, should have a municipal nursery, as

the commissioners have in Washington, who grow the trees which they plant, and can arrange to have them in suitable quantities and of the proper form and size at the time when they are needed. An expert commission would take care to plant the trees in a sufficient quantity of good, well-settled soil. They would set them far enough apart to give each tree an opportunity for its best development; they would water them and mulch them until firmly rooted; they would prune them properly and guard them carefully from all injury by man and beast, realizing that a healthy and vigorous tree is less liable to suffer from insects and disease than one which has been mutilated and enfeebled in any way. If we compare a street properly planted with another, along whose curb a row of spindling saplings from the woods have been carelessly set, we shall realize that the greater portion of the money which has been spent in planting street trees in this country has been worse than wasted.

AMONG the new tenement-house laws for this city, recently passed at Albany as a consequence of the work of the Tenement-house Investigating Committee, of which Mr. R. W. Gilder was the chairman, none are more important than those which relate to the speedy establishment of small parks in the most crowded districts of New York. One bill decrees that the Mulberry Bend Park, the East River Extension, and St. John's Cemetery Park, the formation of which was determined upon some years ago, shall at once be carried to completion. Another bill provides for the expenditure of \$3,000,000 for new small parks in the East Side district lying south of Fourth Street and east of Catherine Street and the Bowery—the most densely populated region in the known world, and at present wholly devoid of open areas or green leaves. A part of each park here established must be finished as a playground; and the law permits school-houses with playgrounds, as well as public baths, to be erected within the opened areas. A third bill provides that "hereafter no school-house shall be constructed in New York without an open-air playground attached to or used in connection with the same." Consequentially, the Board of Education, in purchasing grounds for new schools, has begun to buy additional strips of land for playground purposes, while the Board of Education, the Health Board and the Park Commissioners are already in consultation in regard to the best sites for the East Side parks.

These laws show a wholesome advance in public sentiment, and they indicate that the people who direct the thought and action of the city have come to believe that public parks are quite as essential to the health and comfort and morals of the city as a pure water-supply or a good system of sewage, and that a civilized community can no more flourish without them than without hospitals, libraries, museums, colleges and churches.

Some Unusual Androgynous Flower-clusters.

IN the last volume of GARDEN AND FOREST some notice was taken of the occasional monoecious or polygamous character of the flowering of Poplars and Willows. Androgyny, or the occurrence of both staminate or pistillate flowers together on the same spike, when normally they are separate, is much more common among Willows than is generally supposed, and there are numerous references to it in botanical literature dating back very many years.

It may be worth while to record several observations of variations from the normal habit of flowering among several other kinds of trees. Records of such cases are by no means new, and some occurrences of this nature are given in Dr. Maxwell T. Masters' celebrated work, *Vegetable Teratology*, published by the Ray Society, of London, in 1869. Among monoecious plants it is a common thing to find young trees bearing only male or female flowers, but both kinds of flowers are generally produced as the trees grow older. Abnormal development of the flowers is undoubtedly sometimes brought about by peculiar and unusual

conditions in the situation and surroundings of the plant or in circumstances which affect some portion of it. Often, however, no cause is apparent for any unusual development in blossoming.

PINUS HETEROPHYLLA (CUBENSIS).—The Pines are monoecious, the clusters of pollen-bearing flowers being commonly produced at the end of the growths of the previous season or about the bases of the new shoots, while the pistillate flowers or young cones are usually borne at or near the extremities of the young growths of the season on the longer more vigorous branches and higher up on the tree. Dr. J. H. Mellichamp, a careful observer, at Bluffton, South Carolina, has found large numbers of androgynous flowers on *Pinus heterophylla*. The male flowers or catkins are ordinarily from an inch to an inch and a half in length when fully developed, and the female flowers or cones are from about three-eighths to half an inch long when in condition for fertilization. In the androgynous specimens male catkins or flowers of normal proportions bear on their tips well-developed female flowers or cones of about the ordinary size. There is a marked constriction at the point of connection. In the phyllotaxy or arrangement of the scales, and in every other feature, the flowers of each kind appear perfectly normal. The female flowers probably become properly fertilized, but they wither and dry off with the male portion, and none have been known to develop into mature cones. Regarding this peculiarity in *P. heterophylla*, Dr. Mellichamp writes: "I first noticed this peculiar condition in February, 1893, again in 1894, and now again in 1895, all on the same tree. The tree is a small one, but of good girth, growing on an exposed point of land on May River. It is about twenty-five or thirty feet high, and has been exposed to fire and the submerging of the surrounding land by salt-water in the last great storms, but this was after I first noticed the bisexual flowers in 1893. The tree stands alone, and seems quite vigorous. The abnormal flowers are found chiefly on the lower and middle branches in the proportion of, perhaps, one-tenth of the abnormal to the normal flowers." Since writing the foregoing, Dr. Mellichamp has sent word that he has found another tree of *P. heterophylla* bearing androgynous flowers, this tree being larger than the one first noticed. Since this note of androgynous flowers on *Pinus Cubensis* was written, we have received from Dr. H. Christ a notice of the same thing, based upon Dr. Mellichamp's observations and specimens. It was published by Dr. Christ in *Le Bulletin de la Société Royale de Botanique de Belgique*, xxxiii., deuxième partie, pp. 88-92.

PICEA CANADENSIS (ALBA).—During several seasons two White Spruce-trees, growing on rather poor gravelly soil, have been observed to bear a number of androgynous flowers among innumerable normal ones of both kinds. These androgynous flowers are about of the normal size, and the apical portions of the spikes are occupied by the female flowers or little cones, while the male organs are on the lower or basal ends. In some specimens the male flowers take up fully two-thirds, or even three-fourths, of the spike, leaving only a short few-scaled female flower at the tip; in other specimens the length of the catkin is divided pretty evenly between the two sexes. There is no noticeable constriction or dividing line where the two sexes adjoin. In a flower collected from a third tree this season the male scales extend up among the female scales much more on one side than the other, and the two kinds of scales appear spirally continuous. None of these androgynous flowers have been known to develop mature cones. Somewhat similar cases have been recorded by other observers as noticed on *Picea Canadensis*, *P. excelsa* and *Larix larcina* (under the synonym of *L. microcarpa*), and are referred to in Dr. Masters' work already mentioned. On the trees under notice the androgynous flowers are borne on low branches within easy reach, and these branches are somewhat affected by the cone-like galls of chermes.

BETULA PAPYRIFERA.—Our Birches are monoecious, the male flowers, as partially developed catkins, being con-

spicuously exposed during the winter, the female aments being hidden within scaly buds, and only appearing with the renewal of growth in spring. In the Arnold Arboretum a Canoe Birch, *Betula papyrifera*, in its flowering season in the spring of 1894 produced a female ament two-thirds of the apical portion of which was covered by poorly developed anthers. No other ament was found similarly affected. Dr. Masters refers to androgynous catkins on *Alnus fruticosa* as observed by C. A. Meyer.

QUERCUS IMBRICARIA.—Our Oaks produce the male flowers in catkins from buds on the twigs of the previous season's growth, and the female flowers in the axils of leaves on the new growths in spring. During the flowering season of 1894, Professor Sargent found *Quercus imbricaria* bearing apparently fairly well-developed female flowers among the staminate flowers on male catkins. Of course, these female flowers never developed farther, but fell with the male catkins when the latter had shed pollen and withered. These flowers were found in the Arboretum on a vigorous tree introduced from farther south, as the species is not indigenous in New England.

MORUS RUBRA.—The flowers of the Mulberries are produced in catkin-like spikes, the male and female usually described as in separate spikes, often on separate branch-

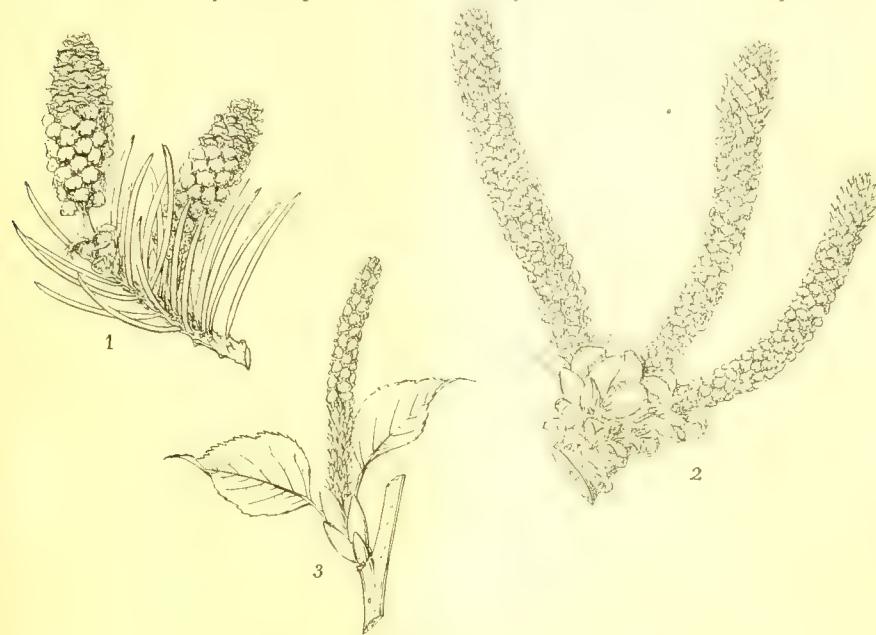

Fig. 33.—Some Androgynous Flower-clusters.

1. *Picea Canadensis*. 2. *Pinus heterophylla*. 3. *Betula papyrifera*.

lets or branches of the same tree, or on separate trees. It is not uncommon for both male and female flowers to appear on the same spike. This condition has been frequently noticed on the Red Mulberry growing in the Arboretum, also on the introduced *Morus alba* or White Mulberry. The flowers of both kinds seem well developed, but no observations have been made as to whether such spikes matured fruit, as they may when female flowers predominate.

The accompanying figures, from drawings by Mr. C. E. Faxon, represent androgynous flowers of *Pinus heterophylla*, from Dr. Mellichamp's specimens, of *Picea alba* and *Betula papyrifera*.

Arnold Arboretum.

J. G. Jack.

Two Wild Vegetables of Merit.

IT is a well-known fact that many of our fruits and vegetables have been developed from plants which in their wild state promised little. These wild products, compared with the results of centuries of cultivation, look so uninviting that we wonder that any attempt to improve them should ever have been made. Naturally, most of our esculent plants are of European origin. It may be true that the eastern hemisphere was favored with a greater variety of food-furnishing plants than the western; as

a matter of fact, however, the wild forms found there are in many instances positively inferior to those of the western continent. In many cases, it must be confessed, we are too far behind in the race to make it wise to neglect what our ancestors have gained, and begin with our wild plants where they began with theirs centuries ago.

Considerable attention has been and is still being given to some of the wild fruits of our country. In fact, we have only to look at the great Black Raspberry and Blackberry fields of New York or the Plum-orchards of the west to see illustrations of fruits which have been known to cultivation only within comparatively recent years.

Not much attention seems to have been given to the introduction and improvement of native vegetables, but there are undoubtedly species which are well worthy of trial in our gardens. One of these native plants, which is already gathered from the fields and used to a considerable extent in the west, is the Wild Lettuce or Lettuces, for, probably, more than one species is used indiscriminately. Both *Lactuca Canadensis* and *L. Ludoviciana* are common on the plains, but the latter is the more abundant about Lincoln. These are gathered and sold in the markets here in very considerable quantities in early spring-time, being chiefly used for greens. They fill an important place for this purpose, for they come in advance of Spinach, and when no other greens are offered in the markets. Whether these Lettuces possess advantages over the Dandelion in cultivation it is not yet possible to say. It seems quite likely, however, that they would better withstand the heat and drought of the summers on the plains. Whether they will take kindly to cultivation, how and when to sow the seed for best results, and other details, must all be learned by trial. It is not likely that either of these species can overtake the cultivated one as a salad-plant, but the leaves are very tender under favorable conditions, though they have a slightly bitter taste. They are sometimes used in combination with potato or other salads, and by some are preferred to ordinary lettuce. Should they withstand the winters in cultivation as well as they do in the wild state, they would have the advantage of being earlier than ordinary Lettuce grown outside.

Another plant apparently worthy of attention is the Ground Plum, or Buffalo Pea of the plains, *Astragalus crassifolius*. This is found abundantly in the draws or low grounds of the unbroken prairie. The plant is a perennial, apparently perfectly hardy and very productive. The fruit resembles gooseberries in size and general appearance. It is borne in numerous clusters very early in the season. It was frequently used by the early settlers when traveling across the plains in wagons in early days, but seems to have largely passed out of use. This could hardly be otherwise, for it is only found in the unbroken prairie. When cooked like string-beans the fruit forms a very acceptable dish. It seems to combine something of the flavor of beans, peas, asparagus and salsify. None of these are very pronounced, however, and it fails in quality rather from a lack of flavor than from any strong or disagreeable taste of its own. Many of our common vegetables, however, have not much in themselves to commend them, and their quality comes rather from the flavor imparted by substances added in their preparation. The fruit requires less time to cook than string-beans, and longer than green peas. If allowed to grow too large the pods soon become tough, and the season, at best, is probably a short one, though it might, through cultivation, reach a larger size before becoming tough. The chief point which recommends the plant for cultivation is the time at which the fruits are

ready for use. Some of the crop from which these opinions are formed was ready to be gathered on May 7th. Even then a few of the fruits were too large to be at their best, although this was far in advance of the season for beans or peas. In fact, the only vegetable which would at all interfere with it is asparagus. This can hardly be an objection, however, for there would certainly be room for two such vegetables at the same season, especially as they are so different in general character.

Experiment Station, Lincoln, Neb.

F. W. Card.

Foreign Correspondence.

London Letter.

CULTIVATED FERNS.—A list of all the Ferns cultivated in the Royal Gardens, Kew, has just been issued, and may be obtained at the Gardens, price sixpence. It contains the names and synonymies in use in gardens of 1,116 species and well-marked varieties of Ferns and ninety-seven of Fern allies (*Lycopodium*, *Selaginella*, etc.); it also contains, in the form of an appendix, a list of nearly six hundred cultivated and feral varieties of British Ferns, the Kew collection of these being exceptionally rich. There is no collection of tropical and temperate Ferns equal in extent to that at Kew, where they have been a prominent feature for at least fifty years. The history of the collection is told in an introduction to the list, which will have a special value for cultivators of Ferns, than which no natural order has a more complicated and irritating nomenclature. The arrangement of the names in the Kew list is alphabetical, and the classification followed is that of Hooker and Baker's *Synopsis Filicum*, the only standard work on the order.

Authorities and countries are given in each case, so that the list will have a value for botanists as well as for cultivators. It is earnestly hoped that the nomenclature of this and similar lists of garden plants, now being prepared with considerable care and pains at Kew, will be adopted by cultivators, at any rate, so that we may all have something like uniformity in regard to the names of cultivated plants. Lists of the Hardy, Herbaceous and Alpine Plants, and of the Orchids, are now in course of preparation, and will shortly be published, the intention being to have in time a complete catalogue of the whole of the vast collection of living plants at Kew, a rough census of which gives the total number as, approximately, 20,000 distinct species and varieties. Of course, the price of these lists is merely nominal, certainly not more than covers the cost of printing and paper, the object of the authorities being to place at the disposal of all interested a reliable standard of nomenclature for garden plants.

THE KEW MUSEUMS.—The contents of the museums of Economic Botany in the Royal Gardens, Kew, are exceptionally rich in plant products of all kinds, their object being "to teach us to appreciate the general relations of the vegetable world to man." There are three separate buildings, one for all Dicotyledonous Plants, another for Monocotyledons and Gymnosperms and the third for specimens of Timber and bulky specimens generally. Museums do not as a rule appeal to the laity, except as places in which to spend a pleasant afternoon, but the Kew Museums have a great attraction for business, especially commercial men, as well as for botanists and horticulturists. The official guide-books to these museums, of which there are three, one for each building, are valuable for the useful information they contain about all sorts of plants and their products. I call attention to them here because the guide to the Monocotyledons and Cryptogams has only lately been published and its contents are of more than ordinary interest. Palms, Scitamineæ, Amaryllids, Liliaceæ, Aroids, Bamboos and Grasses generally, besides, Ferns, Fungi, Mosses, etc., are treated upon, and information about their most noteworthy products is given. I quote the following as a sample paragraph from the hundred pages or so of this valuable little encyclopædia, the price of which, by the way, is fourpence:

"IVORY NUT PALM (*PHYTELEPHAS MACROCARPA*).—A plant with a prostrate stem and leaves often 20 feet long, inhabiting the banks of rivers and rivulets in Central America and New Grenada. The fruits are borne in large globular heads, one of which is here shown attached to the stem. As the seeds ripen they become very hard, like ivory, and are, consequently, known as Vegetable Ivory, and are largely used for making coat-buttons, chessmen, and for various other useful and ornamental articles, as well as for artificial snowflakes in theatres." Samples of the stem and many kinds of articles manufactured from the seeds are shown in the cases.

CATTLEYA FLORIBUNDA.—Plants bearing this name are offered by L'Horticulture Internationale, Brussels, and M. Linden says it is "the most marvelous new Orchid of recent years." He describes it as a possible natural hybrid between *Cattleya maxima* and *C. labiata*, var., having large flowers borne on strong scapes, some scapes bearing as many as twenty-one flowers. Their color is "brilliant dark carmine for the most part," but there are white and other varieties known. The flowering season is from September to December, and as the plants were introduced into the Brussels Nursery on December 30th last, I presume none have yet flowered there, and therefore the description of the flowers has been made by the collector on the spot. *C. maxima*, one of the suggested parents, is a native of southern Peru and Ecuador; presumably, therefore, this region is the home of *C. floribunda*. There is evidence of a growing desire among orchidists to give a mongrel origin to as many new Orchids as possible, *C. floribunda* being a case in point.

CYPRIPEDIUM, GERTRUDE HOLLINGTON.—This is a gigantic flowered hybrid, of which a plant shown in flower last week by Messrs. H. Low & Co. received a first-class certificate. Its parents are *Cypripedium ciliolare* and *C. bellatulum*. It is exceptionally large and robust in foliage as well as in flower, the leaves being nearly three inches wide by seven inches in length, and the petals of the flower are fully one and a half inches wide, creamy white, with purple lines and dots; the dorsal sepal is large and broad, creamy white, with green and purple shading, and the lip is greenish white below, rose-purple above. It was generally admitted to be one of the largest and most striking of the hybrid Cypripediums. It was raised by Mr. Ayling, gardener to Mr. A. J. Hollington, and the raiser of several very handsome hybrids.

W. Watson.

London.

Plant Notes.

Lilacs.

THE past year has been one of the most severe ones which plants in the eastern United States have had to endure for a long time, and it serves to emphasize the good qualities of several shrubs which have not previously had to submit here to exceptionally trying climatic conditions. All the species of Lilac in our gardens are in perfect condition this year, the late-flowering *Syringa Japonica*, *S. Pekinensis*, *S. Amurensis* and *S. villosa* are covered with flower-buds as they have never been before, and the charge that has been made against *Syringa Japonica* and *S. Pekinensis* of being shy bloomers cannot be sustained. It is now apparent that these noble plants only require age to enable them to produce flowers in the greatest profusion. Of the early-blooming species of Lilac, *Syringa oblata* has produced more flowers this spring than it has for many years. It will be remembered that this northern China plant is the earliest of the Lilacs to flower; that its flowers, which are borne in short, broad, compact clusters, are pale purple or mauve color, and very fragrant; that the leaves are not attacked by the mold fungus, which whitens here in summer those of the common Lilac, and that in the autumn they turn to a most beautiful deep vinous-red color. A figure of a flower-cluster of this plant was published on page 221 of the first volume of GARDEN AND FOREST. This

shrub ought to be better known, and every one who has a northern garden should plant one of these Lilacs. The other comparatively rare and little-known early-flowering Lilac, *Syringa pubescens* (see GARDEN AND FOREST, vol. i., p. 415, and vol. vi., p. 266), has also bloomed this year as it has never bloomed before in American gardens, the slender stems being often bent to the ground under the weight of the flower-clusters. This species flowers with the Chinese and Persian Lilacs and with the latest of the varieties of the common Lilac, *Syringa vulgaris*. By some people this is considered the most beautiful of the whole race. The flower-clusters and the individual flowers are smaller than those of other Lilacs, but they excel them all in fragrance, and there is a grace and charm about this plant, which is also a native of northern China, to which none of its more robust relatives can lay claim.

The Lilac season, which twenty years ago lasted a week or ten days, can now be prolonged through six or eight weeks by means of the new introductions which have come to us through the agency of the Arnold Arboretum, and no good northern garden will be complete without representatives of all the species, to say nothing of the new varieties of the old-fashioned *Syringa vulgaris* which French and German gardeners are turning out every year, and which are plants of surprising beauty and the greatest value. The northern United States, of all parts of the world, is best suited to develop the greatest beauty of the deciduous-leaved trees and shrubs of northern countries, and among them all none are more at home or give greater satisfaction than the Lilacs.

The action of cold or of drought, followed by cold, on plants in certain years is not yet well understood. Correspondents in Boston write us, for example, that the common Barberry, which has become entirely naturalized in eastern New England, has suffered severely during the past winter, old-established plants in fields and gardens being often killed to the ground, while the Laburnum, which is always rather tender, and does not flower well in that latitude one year in five, is now everywhere covered with flower-buds. Native shrubs near Boston have generally suffered as much as exotics, and the dead branches which may be seen in the roadside shrubberies testify to a remarkable combination of circumstances adverse to plant-life.

CRATAEGUS PUNCTATA.—So many of our native Thorns are desirable trees that it is difficult to select any one of them for special commendation. There are, at least, half a dozen species which ought to be in every collection of any size, each of them having a character of its own, and an individual expression which is marked throughout the season. We select *Crataegus punctata*, sometimes known as the Dotted Thorn, because, as it was seen last week in Prospect Park, Brooklyn, it was, perhaps, the most interesting small tree there. Its widespread branches stand out mainly at right angles from the trunk so that the deep shadows between the different strata of foliage are generally horizontal, and the head of the tree is often flat-topped. Farther north in Canada these branches sometimes have a spread of forty feet and the trunks are more than three feet in circumference. The best trees in Prospect Park are twenty feet high and broader than they are tall, and just now the corymbs of white flowers borne on the upper side of the level branches give the tree a singularly beautiful effect. Of course, these flowers are abundant, but the clusters do not seem so dense as they are on some other species, nor are they quite as abundant, but the tree is all the more interesting than it would be if the proportion of white to green were greater. This tree is beautiful also in autumn, when its branches are covered with showy fruit, while the foliage turns to a bright orange and scarlet and adds to its attractiveness.

PRIMULA CORTUSOIDES SIEBOLDI.—At this time there is no hardy herbaceous plant that excels this Primrose in the brightness of its flowers. It grows vigorously, and with good treatment increases in size and produces an abun-

dance of flowers each year. It does best in a sheltered situation where it will be shaded from the sun during the hottest part of the day. Mr. Cameron, writing of this flower from the Cambridge Botanical Garden, says that it grows there in a strong, rich, loose loam of a rather damp nature. The flowers are produced on stems eight to twelve inches high, and a single flower measures almost two inches in diameter. The beauty of this plant is lost when only seen with one or two flower-stems. At Cambridge a large clump, measuring half a yard across and bearing fifty or sixty stout stems with large umbels of flowers, shows how effective it can be. It is a strictly herbaceous perennial; the coarsely toothed, ovate leaves die down in the fall and come up again in the spring. The flower is very variable, and a large number of forms have been raised since it was introduced from Japan thirty years ago. One named grandiflora is in flower now, and it is a magnificent plant. Although its habit is the same as that of the type, the flowers are quite distinct, being much brighter and slightly larger. In the fall this Primrose should be covered with dry leaves and a few pieces of board to keep them from being blown away. In spring, whenever there are signs of growth, the covering is removed.

STELLARIA HOLOSTEAE.—This is now the best white-flowered plant in the front row of the herbaceous border. When its flowering season is over it looks rather weedy, and it grows so freely that if not kept in subjection it very soon destroys the other low plants growing near it. Nevertheless, it is a good perennial and deserves a place in the choicest borders. The white, star-like flowers measure three-fourths of an inch in diameter and grow in cymes on the stems. The flowers are produced very plentifully and the plants are completely covered with white flowers. When massed together this plant is very effective, and Mr. Cameron suggests that it can be used for a spring bedding-plant when white flowers are scarce.

A NEW IRIS.—We have received from Mr. Gerard flowers of a new Iris, the production of Professor M. Forster, a cross between *I. paradoxa* and *I. variegata*. We are not aware that it has been named, but, according to Professor Forster's usual nomenclature, this would be *I. Parvar*. The plant is especially interesting as a cross between an *Oncocyclo* Iris and one of the ordinary bearded Irises, with a quite different habit. *I. paradoxa*, which is rare in cultivation, is one of the dwarfest of *Oncocyclo* Irises, with narrow rhizomes and quaint purple flowers with a very marked disproportion between the standards and the falls, even for this section, where the falls are always smaller than the standards. *I. variegata* is the common Iris with large rhizomes. The type has yellow standards and madder-brown or reddish brown falls. The new Iris has a rhizome—short, creeping and thick. The leaves are a foot long, falcate, light green and slightly glaucous. The stems are about a foot and a half tall, and bear two long, flat, oval scapes, the terminal being double-flowered, the lateral having a single one. The standards are only slightly larger than the falls, have beautifully crimped edges, and are of a rich vinous-purple, with a median vein of darker color and white linings on the inner base. The oblong falls, not much recurved, have a deep rich reddish brown lip, and are lined on the edges in the same color on a white ground. The beard is formed of fine hairs of a lighter hue. The fall is covered with very fine hairs, giving it an effect of velvet. The styles are light reddish brown. Altogether it is a flower of rich color and striking beauty. This has been grown by Mr. Gerard two years, and as it has proved to be of vigorous growth and perfect hardiness, it is a welcome addition to the garden. It is not a deciduous variety, and requires none of the special treatment in the way of dryness which the *Oncocyclo* Irises need.

HEUCHERA SANGUINEA.—This handsome plant of the Saxifrage family is now well known as one of the best small hardy plants introduced in recent years, and much testimony as to the esteem in which it is held has been published in GARDEN AND FOREST, especially since it has been

found to be reliably hardy. It is easily and rapidly increased by the crowns which it produces in abundance, and also by seeds. Growers of seedlings have been rewarded by the production of new forms differing in tone of color and size of flowers. One of the best of these forms, which has been extensively propagated, is known as Splendens. In this variety the color is very intense and the flowers about twice the size of the type. Nothing could be prettier than the arching stems of this plant bearing a row of gem-like flowers of beautiful color. To speak more exactly, it bears along arching stems, on the ends of short pedicels, clusters of three and more flowers, which are of a bright red of the tint known as cerise.

Cultural Department.

The Russian Tree Fruits in America.—I.

ONE who attempts to trace the origin of different varieties of orchard fruits will find the investigation difficult and wearisome. This is not surprising in the case of native fruits, which are usually known and valued for some time in a single neighborhood or town before attracting attention elsewhere. But in the case of imported kinds it would seem that there should be less difficulty. Yet our earliest New England authority, and it is a most excellent and painstaking work, Cole's *American Fruit Book*, credits the Duchess of Oldenburgh Apple to Russia, Red Astrachan to Sweden, and fails to notice either Tetofsky or White Astrachan. Yet it is generally supposed that they were all brought to this country from England at or about the same time. Mr. Cole was the editor of the *New England Farmer*, supposed to be the oldest agricultural newspaper in America; and the importation of these Apples is credited to the Mannings, of Reading, Massachusetts. Inquiry reveals the fact that there are in that town two families of that name, yet not related, and as, by correspondence, I find that one family declines the honor, I am left to the conclusion that the true source of this importation is the family now represented by Mr. J. W. Manning, from whom I received the Tetofsky in 1872. At about the same time I received the Duchess of Oldenburgh from Mr. S. L. Goodale, a prominent horticulturist of Saco, Maine, while the Red Astrachan was sent to me by the great nursery firm of Ellwanger & Barry, of Rochester, New York, at the same time, or a little earlier. This variety, notwithstanding its Russian origin, has not proved hardy against the cold winters of north-eastern Vermont, which is hardly surprising, when it is remembered that Astrachan is the southernmost province of Russia, with a climate, judging by its products, not unlike that of New Jersey. Some further correspondence with Massachusetts parties leads me to the conclusion that the above-named Russian Apples reached this country from English growers, who, in their turn, obtained them from Sweden, which was probably the reason for the assignment of the Red Astrachan to that country by Mr. Cole.

Of the above-named importations only three varieties, the Oldenburgh, Tetofsky and Red Astrachan, have had a wide distribution in America. It was soon discovered that the Oldenburgh and Tetofsky could be grown successfully much farther north than any other well-known sorts, and it was to these that the title of "Iron-clads" was applied; first, I think, in Minnesota, after one of the "test winters" of that region had cut off nearly every other sort of cultivated tree fruits.

At about the same time at which I became practically acquainted with this cold-resisting characteristic of these Russian Apples, disappointments in Wisconsin and Minnesota, resulting from the widespread destruction of many young orchards by severe winters, gave rise to a strong demand for a more thorough and extensive trial of the tree fruits of north-eastern Europe. Quite a number of Americans were at that time engaged in scientific and industrial service under the Russian Government, and through these a considerable importation was made on private account. Representations were also made to the national authorities; and after the expenditure of the usual amount of red tape, a large importation of Russian Apple-trees and cions was made, which on arrival were distributed from Washington. This distribution was made with so little judgment that more than half, perhaps as much as two-thirds, of the whole importation was lost. The cions which were sent direct to farmers were generally a total loss, as not one farmer in five hundred throughout the country has ever learned the simple art of grafting, which every farmer's boy should know by the time he is ten years old. But enough survived, and in time came to fruitage, to satisfy intelligent fruit-growers that here was a race of Apples quite

new to America, and capable of far greater resistance to cold than the fruits of western Europe, which constituted our sole stock at that time, with the few exceptions noted above.

Newport, Vt.

Pelargoniums.

AT this season of the year no class of plants compares with Fancy Pelargoniums for decorative purposes in the greenhouse or conservatory. They are by far the most gorgeous of the Geraniaceæ, and no one having a greenhouse should be without them. They also make admirable window plants. For several years their cultivation has been much neglected in America, and even now, when they appear to be regaining some of their lost popularity, there is hardly a florist who catalogues more than two or three varieties, and these are usually not the best ones, so that the only way to secure a good selection is to import the plants. For market purposes, Pelargoniums have never been very popular, and it is surprising that they have not received more attention from florists. They are easily cultivated, and can be grown almost as cheaply as ordinary bedding Geraniums. Last year I persuaded a neighboring florist to grow a few dozens in five and six inch pots. The plants sold readily, and his customers were perfectly satisfied with their behavior as window or piazza plants. In England enormous quantities of Pelargoniums are grown for the large flower markets, usually in six-inch pots, and thousands of plants are sold each day in Covent Garden alone during the height of the season. Few cottagers in England or Scotland who grow window plants are without a Pelargonium. Owing to the cooler summer weather there, the plants do not bloom until September. In this country they are usually spent by July, but this gives two months of constant bloom, a much longer time than a Cineraria or Calceolaria lasts.

Cuttings inserted during September or October can be easily grown into nice specimens by the following May and flowered in six or eight inch pots. We place our cuttings in boxes of sand provided with ample drainage, and treat them in the same way as ordinary Geraniums. The plants should be grown in an airy house and kept well up to the light. Green aphis is their chief enemy, and to combat this we spread some tobacco stems among our plants and give a fumigation about once in ten days. The best time to give a thorough fumigation is just before the blooms start to open, as tobacco smoke causes most of the petals to drop.

Although young plants can be grown to sufficient size in one season for most purposes, older ones make fine specimens for a show-house. After the blooming period is over the plants can be stood outdoors and kept rather dry until the middle or end of August, when they may be pruned back. After pruning they should be watered freely at the root to encourage the plants to break, and when shoots an inch or more long have been made they can be shaken out and repotted into pots of the same size, or a size smaller than they were in before. The soil should be well shaken from the roots, and the roots themselves pruned back. The plants should not be exposed to cold rains or early frost. For compost we use two-thirds turf loam and one-third well-dried cow-manure. Some bone-dust may also be advantageously mixed in, and a shovelful of sharp sand to each bushel of compost. If extra large specimens are desired the shoots must be well staked out. In England specimen plants are often three to four feet across, and the shoots are tied down to a wire or wooden circular frame above the top of the pot. Magnificent specimens of Pelargoniums are shown yearly, especially at the York and Manchester shows. Such plants, though displaying marvelous cultural skill, have a rather formal appearance, and more naturally grown specimens are preferable.

Pelargoniums are gross feeders, and liquid-manure can be as freely used as with Chrysanthemums. During the blooming period they require plenty of water. We place a saucer under each pot. If a plant gets thoroughly dry at the root a loss of foliage follows, and its appearance is spoiled. While flowering the portion of the house where the Pelargoniums are kept should be well shaded and be as cool as possible.

Of late years great improvements have been made in this class of plants, especially in the new hybrid semi-double sorts. These usually have seven and eight petals each, and last much better than the single ones. Good varieties of Pelargoniums are Mrs. R. Sandiford, Volonté nationale alba and Princess Teck, among whites; of colored ones the following are good: Madame Thibaut, Kingston Beauty, Dr. Masters, Triomphe de St. Mandé and Volonte nationale.

W. N. Craig.

[Last year we saw some exceptionally well-grown Pelargoniums at the nurseries of Messrs. Turner, at Slough,

Taunton, Mass.

England, and also at one of the Regents Park exhibitions. At our request, Mr. Charles Turner sent photographs of several plants, one of which is reproduced on this page. This plant is not so completely covered with flowers as many of the others were, and for that reason it is rather more interesting, since the foliage which appears between the flowers gives them distinctness of outline, and helps them in every way by furnishing relief and contrast. The

do this plant much better than they can in England, and this is remarkable in that the standard works on Orchids seem to insist on an equable temperature the year through, and it is the more surprising that with our extremes we can succeed so well with a plant enveloped in mists and rain for the greater part of the day in its South American home. We have one advantage over transatlantic cultivators in the tobacco-stems that are so easily obtained for the purpose of keeping down thrips, a pest to which *Miltonia vexillaria* is specially subjected.

Fig. 34.—*Pelargonium, Amethyst*.—See page 226.

variety in the illustration is known as Amethyst, a very dwarf and floriferous sort. The top petals are deep maroon, beautifully edged, and the others are a rich purple.—Ed.]

Miltonia vexillaria.

THE picture of a fine variety of this plant in GARDEN AND FOREST for May 15th reminds me of the ease with which this Orchid may be cultivated in American gardens. I was told by a distinguished English visitor the other day that we

Our plants were infested when received, but a few dustings of tobacco in the axils of the leaves and tobacco-stems spread under and round the plants as they grew, soon cleared them of insects, and insured good, clean, healthy growth. This *Miltonia* is another of those Orchids that can be counted on to increase both in size and value each year. If carefully placed in the coolest house in the summer months, and at the cool end of the Cattleya house, where a temperature of fifty to fifty-five degrees can be obtained in winter, shaded from bright sunshine at all times, except in the depth of winter, they grow without difficulty.

After the flowering period the plants will need a little rest to recuperate, but water must not be withheld, and soon the young growths will start away, and this is the time to repot, which will be about September, when cool nights will insure a good start. For a potting compost we use moss and Fern-root, with a little dried cow-manure from the pasture. They seem to like this and manure-water at every second or third watering after the roots have begun to run through the potting material, but it should be applied well diluted.

There is no form of decoration to which these lovely flowers will not lend themselves, either as cut blooms or in the pots. The graceful, arching sprays of pink flower shades vary from a rich deep rose to the pure white of the unique "Fairy Queen," but even the common forms are beautiful enough for any garden. Many of our plants are producing four spikes from one bulb, and one of these single bulbs has forty-one flowers on the four spikes, so the free-flowering qualities of this *Miltonia* can hardly be overstated.

Another very fine *Miltonia* is *M. Roezlii*, and its white variety. The flowers of this plant are very fragrant and have the same outline as *M. vexillaria*, but it requires a warmer house than the latter, as it comes from a much lower elevation, from 1,000 to 2,000 feet, while *M. vexillaria* grows at an altitude varying from 4,000 to 7,000 feet above sea-level, so that it will easily be understood that a house at least ten degrees warmer in winter is necessary for *M. Roezlii*, otherwise it is of the same easy culture and flowers at the same time of year.

These two *Miltonias* used to be and are still known in catalogues as *Odontoglossums*, but of recent years they have been removed to the genus *Miltonia* with which they have a true affinity. Owing to the recent introduction of these plants there is a reasonable hope that other large-flowered forms of *M. vexillaria* will soon be obtainable.

South Lancaster, Mass.

E. O. Orpet.

Some Herbaceous Perennials.

POLEMONIUM REPTANS is a native plant that is giving good satisfaction this year, and every little stem is loaded with flowers. It is eight or ten inches high, and its drooping beautiful blue flowers are produced in loose panicles. The spreading stems are well clothed with pinnate leaves, and give the plant a neat and compact habit. It grows well in ordinary garden-soil, and likes a position where it is not shaded by trees.

The Rocky Mountain Columbine, *Aquilegia caerulea*, is one of the best in this genus. It is a choice perennial, and deserves more attention than some of our commoner forms. All the Columbines are graceful and beautiful, but this species is especially so. Its special beauty is in the nearly erect blue and white flowers. They are nearly three inches across, and the nearly straight, green-tipped spurs of the flower measure two inches in length. The plants grow to be twelve or fifteen inches high, and the leaves are large and binate. *A. caerulea* does well in the border or rockery. It is, however, not a long-lived plant; seed should, therefore, be sown annually, so that young plants may take the place of such as fail to come up in the spring.

On the north side of an *Arbor-vitæ* hedge a good strong plant of *Orchis latifolia* is now showing, as it has in successive springs, strong spikes of purple flowers. This plant does well in such a situation in deep rich moist soil. It does not like to be disturbed often, and when once established should not be moved for a number of years. It grows about fifteen inches high; its leaves are lanceolate, spotted with purplish black. The flowers of this English plant are produced in dense spikes, and they last for a considerable time.

Harvard Botanic Garden.

Robert Cameron.

Correspondence.

Is Parsnip Poisonous?

To the Editor of GARDEN AND FOREST:

Sir,—In your issue of May 1st Dr. Halsted has some interesting notes on poisonous plants. What Dr. Halsted says in regard to poisoning from Cowbane, *Cicuta maculata*, is to the point. The cases of poisoning from this plant are so frequent, not only in this state, but elsewhere, that I have prepared a paper on the subject, which will soon appear in our station bulletin. I have looked up with considerable care cases of poisoning, and I have yet to learn of a case of fatal poisoning from Parsnip running wild or "Wild Parsnip," *Pastinaca sativa*. I have requested specimens, and have asked to receive information of authentic cases, but they have not turned up. We have the best of evidence that the plant is not poi-

sonous. No one can question the evidence introduced by Professor Frederick B. Power,* whose careful scientific work along the lines of pharmacy is well known. Professor Power failed to find any poisonous substance in "Parsnips running wild"; boiled roots fed in considerable quantity to a cat showed no symptoms of poisoning. His associate, Dr. Cramers, insisted upon eating one-half of a raw parsnip which was sent to him from West Salem, Wisconsin, and which were supposed to cause the cases of poisoning in question, but no ill effects followed.

Again, Dr. Brown, of Sheboygan, Wisconsin, had prepared enough wild parsnips for a good dinner, which he ate, and, if I remember correctly, his whole family ate of it, but without any ill effects. Now, these Parsnips had been running wild for fifty years.

I have myself eaten raw parsnips "running wild," but could observe no injurious effects whatever. I have been trying in a limited way to demonstrate the non-poisonous properties of parsnip, and that people should especially guard against *Cicuta maculata*. I believe it is largely a myth that parsnip is poisonous. It is possible that some people may have peculiar idiosyncrasies for parsnip just as for celery, but to call the plant poisonous is a mistake.

Agricul'tl College, Ames, Iowa.

L. H. Pammel.

Agaves in Southern California.

To the Editor of GARDEN AND FOREST:

Sir,—In reference to the beautiful engraving of *Agave Huachucensis*, in your issue for May 8th, allow me to say that *A. applanata* has frequently bloomed during late years in southern Europe, and, as far as leaves and habit are concerned, it appears to be totally different from the subject of your picture. *A. applanata* is a larger plant, with a smaller number of leaves, which are nearly triangular in shape, of an ashy gray or whitish color, with strong decurrent dark red mucros and similar spines. Two-year-old plants of *A. Palmeri*, from seed received from the Missouri Botanic Garden, are certainly not to be confused either with *A. applanata* or with grown-up specimens of *A. Parryi*, received from the same source, and from Professor Tourney, of Tucson, Arizona, who writes that in his opinion *A. Parryi* and *A. Huachucensis* have been badly mixed together.

Every one who takes interest in the progress of botany and of practical horticulture in the United States will concur in your view that a large number of plants can be thoroughly studied only if grown in the open and in conditions similar to those of their natural homes. Such a station as suggested, or better still, something like an Arnold or a Shaw endowment, we ought to have in southern California, a location which offers so many advantages to growing in the open all sorts of plants from many climates. Meanwhile we are working steadily here to increase the nucleus of such a garden. Of the above-mentioned plants we have already of *Agave* thirty species; *Fourcroya* and *Beschorneria*, eleven species; *Dasyllion*, *Beaucarnea* and *Nolina*, seventeen; *Yucca*, fifteen; and among them such rare ones as *Agave angustissima* and *A. parviflora* (illustrated in GARDEN AND FOREST), *A. vestita*, from Guadalajara, *A. Margaritae*, from Lower California, *A. Franzosini* and *A. Henriquesii*, recently described by Baker; *Nolina Beldingi*, from the extreme southern point of the Peninsula of California; *Yucca gigantea* and *Y. Guatemalensis*, from Central America. At the rate all plants are growing here it will not take many years for most of them to bloom and fructify, thus affording ample material for study and identification.

F. Franceschi.

At the South Orange Nurseries.

To the Editor of GARDEN AND FOREST:

Sir,—At a recent visit to the establishment of Mr. W. A. Manda I noticed, among other interesting plants in flower, *Iberis sempervirens superba*, which is apparently an exceptionally good variety of the hardy Candytuft. It was sent out by Backhouse, and has flowers of the purest white in dense heads, and the individual flowers are of good size. *I. sempervirens* is evergreen, more reliable for hardiness than *I. Gibraltarica*, and this variety is of a bushy habit, and evidently a fine subject for the garden. Mr. Manda had also in flower *Campanula persicifolia alba grandiflora*, which formidable name has been given to a superior form of this common Bellflower, which is too uncommon in hardy-plant gardens. The corollas of this variety were much deeper and more bell-shaped than those of the type, which is a favorite plant wherever grown.

*See *Pharm. Rundschau*, 1891, pp. 162-165. *Ibid.*, 1886, p. 161.

I found also in flower the attractive *Genista Andreana*, which, as GARDEN AND FOREST has before noted, is an improved Broom with large yellow flowers, having bright chestnut-colored wings, and of evergreen habit.

Erica pygmæa is a species of Heath not before seen by me. It forms a dense mat of dark green, scarcely rising above the surface of the ground, and later on covered with pleasing purple flowers. Good mat-plants are one of the attractions of the hardy garden, and where Heaths will thrive this distinct dwarf species should be a welcome plant. It seems to be of easy propagation by division. There were numerous other hardy plants in flower, mostly familiar subjects, and for a dense mass of brilliant yellow, *Achillea tomentosa* was noticeable.

The loss of *Anemone Japonica* seems to have been complete here last winter, and this, I think, has been the general experience in this section. *Hypericum Moserianum*, as usual, was badly cut down, but is now beginning to shoot at the base. This beautiful plant, I think, may now be considered root-hardy only in this section, and, therefore, classed among hardy herbaceous plants. Greenhouses, with the outside temperature of ninety degrees, are not places where one cares to linger, but I noticed, in a hurried review, that Mr. Manda's new hybrids of *Rosa Wichuraiana* were doing admirably, and were as vigorous as the type. These are crosses with some of the perpetual Roses, and have single or semi-double flowers of large size. *R. gigantea*, growing on a bench, I hope to see in flower and report on later. Some strong plants of *Myrosmia cannæfolium*, which is being advertised as the white Canna, with most remarkable qualities, reminds me to ask whether any one has succeeded in flowering it. This plant was put out by Dammann in 1893, with most attractive claims. It is very obdurate in showing its flowers under any conditions of treatment. It is suspiciously like a *Hedychium* in habit and appearance, and its identity will be in question until it flowers.

Meetings of Societies.

Meeting of the American and New Jersey State Forestry Associations.

THE idea of holding peripatetic forestry meetings, and combining instructive excursions with sessions for the discussion of topics with special relation to the regions traversed, was first carried out in August of last year, when the American Forestry Association met under the auspices of the New Hampshire Forestry Commission in the White Mountains. The success of that meeting, both from the social and forestal point of view, suggested a repetition this spring in southern New Jersey, where, with the formation of the South Jersey Woodmen's Association and the New Jersey State Forestry Associations, the movement for a rational treatment of the forest-cover of that state had just received its first impetus.

The meeting began with an evening session at Camden on May 15th; when Mr. B. E. Fernow delivered his richly illustrated lecture, "The Battle of the Forest," discussing the evolution of forest-growth, the forces of nature with which the forest has to contend in order to establish itself and the methods and means employed in this warfare, the evil results of improper partisanship on the part of man, by which not only is the forest resource itself decimated and deteriorated, but soil and water conditions are injured sometimes beyond redemption. Numerous views from this continent and from abroad illustrated the points made.

The next morning found the party on the way to Cape May, over the level sandy alluvial plains of southern New Jersey. The first observation of interest was, that on both sides of the railroad, about two rods away from the road-bed, there was roughly plowed a strip of land about a rod in width, a "safety strip" to protect the forest-growth against the spread of fire from the railroad. This precaution, which has been quite effectual, is a result of the intelligence of the adjoining property holders, who insisted on holding the railroad company responsible for damage in case of fire, and the company found it cheaper to prevent than to pay damages. Colonel Fox, Superintendent of the New York State Forests, who was of the party, stated that on the much-talked of Webb Road in the Adirondacks, another system had been successfully pursued during last summer: a hand-car with a crew and all necessary appliances to put out fires following each train.

If only the owners of forest-land had a proper conception of the value of their property and of the great damage which these fires inflict—to the soil more than to the timber—they would soon be able to get rid of this one source of conflagrations.

The forest-growth of this part of New Jersey is, to be sure,

mostly not of immediate economic value, the heavy timber of the original growth which once covered these alluvial sands having been entirely removed from most parts long ago; a second growth has taken its place, mainly of various Oaks, Yellow Pine, *Pinus rigida*, and occasionally Red Cedar and Holly, supplanted by White Cedar in the wetter portions, repeatedly injured by fires, yet bound to maintain itself, and sometimes in quite thrifty condition. With the fires kept out, by a judicious use of the axe, gradually culling out the inferior kinds and giving advantage to the better classes of timber, these abused areas would, without hardly any outlay, in twenty-five or thirty years become a valuable property. A basket factory, using Sweet Gum, and a sash, door and blind factory, using White Cedar, both situated along this line, give evidence that even now, at some distance from the road, virgin forest-supplies are not entirely exhausted, while the thrifty surroundings of Vineland and of the Russian colony established by Baron von Hirsch show the capabilities of the soil under careful cultivation.

At Cape May the party enjoyed an afternoon stroll on the beach and an exchange of experiences and opinions regarding forestry problems. In the evening an attentive audience listened to an address by Mr. E. A. Bowers, Assistant Commissioner of the General Land Office, on the conditions of the Government forests and the duty of the Federal Government with regard to them. Mr. Bowers took the position that every citizen was a part owner, and hence interested financially in the great national timber domain situated on the western mountains, in a region which for its prosperity is dependent largely on irrigation, and hence on the storage of water-supplies under the forest-cover.

Friday morning saw the party early on their way to Atlantic City. The forestry feature of interest en route was the sand dunes of Seven-mile Beach, below Avalon, which were visited by special train, kindly furnished by the Pennsylvania Railroad Company. The problem of the sand dunes could here be studied in all its phases. The forest-cover once removed from the shore, the light sand is given over to the play of the winds, which drive it landward, and a wall of sand twenty to thirty feet in height is thus gradually moved, progressing from year to year more or less rapidly. A small strip of forest-growth two hundred yards or so from the shore is now impeding its progress, and yet the dune is said to advance at the rate of one foot a year, covering this protective belt. The sand wall is some twenty-five feet high, with a slope of about forty feet on the leeward side encroaching on the timber, which consists of White Holly, *Ilex opaca*, over one hundred and fifty years old, and Red Cedar, with occasionally a Sassafras, an Oak or a Wild Cherry intermixed. The timber is only thirty-five feet high; the sharp sand particles driven by the wind cut off and shear like a hedge the tops of the trees, which are hardly ten feet above the highest level of the dune. It is interesting to note how long some of the submerged trees can retain their vitality, Cedar and Hollies, covered up within ten feet of their tops, still showing life, while the Oaks and Sassafras are dead and crumbling, and the Cherries have shed their seed, giving rise to a new generation on the dune itself.

Where the forest has been removed the action of the wind reaches farther inland, but where the forest-barrier is intact the dune seems to have become quiet enough to allow a natural cover of Sand Grasses to establish itself, which may in time stop its further shifting. Since, however, the land belongs to a real-estate boom company, it is likely that the lots will be considered too valuable to keep the tree-growth intact, and its kindly offices unappreciated, it may have to go as elsewhere, with the assurance that the lots themselves, with houses and improvements, will gradually be drowned in the sand. Even the bathing-beach, which in such places is usually the only attraction, has in many places been spoiled, the sand being blown off and a muddy bottom remaining. The intimate relation of forest-cover to almost all other kind of business was here strikingly suggested, just as on the plains and in northern New Jersey the needs of the city of Philadelphia and other cities and towns for desirable supplies of drinking-water would have suggested the close interest of their citizens to the forest-conditions of those regions.

A beautifully illustrated lecture by Professor J. T. Rothrock formed the feature of the session at Atlantic City. The lecturer spoke of the habits, habitat and value of various forest-trees of eastern states, and laid special stress on the fact that forest-growth was destined to be relegated to the agriculturally poor soils and situations.

Owing to rain it was decided to postpone the sessions at Lakewood to a more favorable season, when it might be possible to arrange for a continuation of the trip through the

northern part of the state. Suitable resolutions of thanks were passed to those who had contributed toward the success of the meeting, notably to Mr. John Gifford, whose good nature and pleasant courtesy was never ruffled by disappointments.

Notes.

London is constantly adding to its park area, and Lincoln's Inn Fields has at last been secured as public property, and is to be transformed into a public playground. The price paid for this area was twelve thousand pounds down, and a pound a year rent for the remainder of the time for which the lease of the Fields has still to run—a period of some 600 years.

The United States Consul at Messina reports that from November to the middle of March the export of oranges from that port was about 340,000 boxes against only 95,000 boxes the year before, and taking the season through considerably more than four times as many oranges were probably sent to the United States as were shipped the previous year. Of course, this increase was due to the failure of the Florida orange crop.

Mr. J. H. Hale writes to the *Fruit Trade Journal*, that after a careful inspection of 100,000 Peach-trees in his orchard, he finds no trace of disease or insect, so that the promise of perfect fruit from Georgia is fair. The dropping of the fruit is all over, and in some cases nature has thinned a little too much, although generally it is necessary to do more thinning, an operation which is essential if first-class fruit is to be secured.

It is estimated that in Georgia, Alabama and Florida about 22,000 acres of land will be planted to Water Melons. This means, with a favorable season, that 10,000 car-loads of melons will be shipped, and since an average freight train is composed of twenty cars, five hundred train-loads or more must be moved, which will make an average of twelve trains every day in the week for six weeks. Altogether, it will require unusual activity to get these millions of melons started on their journey to northern markets.

The Globe flowers, which range in color from the palest citron or almost white to deep orange, need no commendation as they are now to be found in almost every garden of hardy herbaceous plants. According to *The Gardeners' Chronicle*, Dr. Stuart, of Chirnside, Scotland, has succeeded in crossing *Trollius Europeus* on our American wild *Trollius*, which does not deserve the name of Globe Flower, since the pale greenish yellow sepals do not incurve, nor is the flower rat all showy. Some of these crosses, however, are said to be remarkable, since they are of large size, of a deep color, and so double that they are said to look like orange-colored Roses.

Sugar corn from Bermuda now costs fifty cents a dozen ears; peppers from New Orleans, which have been coming in for a week, seventy-five cents a dozen, and large egg-plants from Florida seventy-five cents each. Mushrooms, on account of the plentiful supply due to the hot weather, fell within a week from \$1.50 to thirty-five cents a pound. They sold on Monday for sixty cents. South Carolina now supplies okra; Maryland, Virginia and New Jersey are sending peas, and Long Island furnishes beets and carrots. The scarcity of vegetables several weeks ago after the unseasonably cold weather led to various experiments, and yesterday some hot-house tomatoes arrived from the Isle of Guernsey, too late to command the highest prices.

A bulletin on Chrysanthemums has been prepared by Michael Barker, of the Cornell Experiment Station. It is chiefly a record of the habit of the leading varieties on the market in 1894, and it gives an account of the behavior of the more prominent ones of the two hundred kinds tested. The report is written from the standpoint of the florist rather than of the amateur gardener. Mr. Barker concludes that for the purposes of American growers American varieties are superior, as a rule, to those of foreign origin. The best ones tested at Cornell for commercial purposes, among the yellow varieties, were Eugene Dailedouze and Major Bonnaffon; white, Mayflower and Marie Louise; pink, Mrs. E. G. Hill and Laredo; bronze, Charles Davis and Ingomar.

European critics, according to their mood, have long pitied or scorned American architecture for its persistent use of wood as a building material, even in structures of considerable size and pretension. It is curious to find, therefore, that

wooden buildings of certain sorts are now becoming the fashion in England, where cheapness does not recommend them as it does in this country. The new move has been inspired, however, not by the example of America, but by that of Scandinavia, where many fine old public buildings and churches, as well as private houses, are wholly constructed of wood. The Prince of Wales, we are told, is interested in an Anglo-Norwegian company created to bring wooden structures into fashion in Great Britain; and is having a number of picturesque examples, in the way of houses and lodges, erected on his own estates at Sandringham, and the greater part of Mar Lodge, the autumn residence of his daughter, the Duchess of Fife, has been constructed of wood.

In *The Speculum*, a journal published by the Michigan Agricultural College, Professor Beal gives a history of eleven trees which were planted on Arbor Day, 1887 with a good deal of ceremony. There were elaborate exercises in the chapel; the trees were planted, one in memory of each of the four classes, the different fraternities, the baseball nine, etc., and the President of the college, as the procession passed from tree to tree and saw that they were properly placed, guaranteed that each one should be well cared for. Professor Beal takes up the history of each tree, and in summing up their present condition finds that only three of them are thrifty, four are feeble, three are quite dead and one is about to die. None of the living ones are marked by any label, nor is the history of any of them to be found in the report of the President or in the college paper. Judging from this, Professor Beal is probably right in saying that the chief value of an arbor day, such as the one celebrated in 1887 at the Michigan Agricultural College, was sentimental and that the sentiment was ephemeral.

One of the most attractive floral displays ever made in an American garden was seen in the Arnold Arboretum last week, when the Lilacs were in bloom. About one hundred and twenty varieties of *Syringa vulgaris* were in flower. The collection occupies a wide bed, stretching for more than nine hundred feet up a rather steep slope, along one of the principal drives, and the color of the flowers is well brought out by a high green slope behind and parallel with the bed. Among the most attractive of the varieties in this collection are Marie Lagrange, white; Rubra insignis, dark red-purple; Trianoniana, purple; Madame Briot, red-purple; Geheimath Heyder, pale reddish blue (very large compact panicle); Alba grandiflora, white; Charles X., dark red-purple (an old variety, but still one of the very best); Emil Liebeg, pale blue; Bertha Dammann, white; Virginialis, white; Ambroise Verschaffelt, flesh color; Gigantea, mauve; Carsli, dark purple-red; Maxime Cornu, pale blue (double); A. Lavallée, pale blue (double); Lamarck, pale blue (double); Ludwig Späth, dark red-purple (very late); Philamon, dark red-purple; Alice Macguery, purple-red; La Tour d'Auvergne, dark red-purple (double, very large compact panicle); Félicite, pale flesh color (semi-double); Madame Moser, white; Tournefort, dark purple in the bud, opening bright blue (double).

Large and bright purple-black Tartarian cherries, from California, cost at retail twenty-five cents a pound, while immense cherries known as Centennial, almost equal in size to the apricots now coming from that state, cost forty cents. This showy variety is a California seedling fruited for the first time in 1876. It is of an amber color, freely splashed with dark crimson. Its meaty flesh is remarkably sweet and of excellent flavor, and while the fruit is juicy it has the good market qualities of keeping well and of carrying in good order. The best of several small lots of cherries from North Carolina compare unfavorably with those from California, the highest price for these being twenty cents a pound. California peaches have already been seen here in small advance lots, a box containing eighty fruits selling for \$4.00 at wholesale. The season for citrus fruits from the Pacific slope is nearly ended, and as they come in refrigerator-cars they quickly melt when exposed to the heat. The few Mandarins remaining in the retail fruit-stores are offered at thirty cents, selected Navel oranges at sixty to seventy-five cents, and large shaddocks at \$2.00 a dozen. Huckleberries from North Carolina are quite plentiful and of fair quality for the time of year; the best bring twenty-five cents a quart. A few native plums and some peaches came from Georgia last week, but were not sufficiently ripe to bring good prices. Muskmelons are coming from Florida, but very few of them are of the best quality. Except occasional lots of Russets from the interior of New York state, no more apples are likely to arrive. The barrel stock on hand is being divided into baskets holding something more than a half bushel. Ben Davis is the latest red apple offered.

The Defacement of City Parks.

A FEW weeks ago the Board of Park Commissioners in this city thought they could safely throw open to the public a few small areas of turf in Central Park. They gave notice of this fact, and the reporters of the various newspapers at once began to interview them on the subject. The statements of the commissioners were guarded and cautious. They said nothing which could fairly be interpreted as an indication that any rigor of administration was to be relaxed. They simply said that inasmuch as on certain days some of the lawns were free they proposed to try the experiment with a still larger area of turf. But the bare hint that visitors were to be allowed freedom of access to portions of the park from which they had hitherto been excluded, seemed to arouse a spirit of lawlessness in many visitors which had hitherto slumbered. Testimony is abundant to the effect that the park has suffered serious defacement since this permission was granted, the chief injury being done to shrubs and herbaceous plants in bloom. Branches of showy bushes, like the Snowballs, for example, were carried away by the armful in spite of the police.

A significant fact was stated by a park policeman, who said that for the first few days after the lawns were thrown open people could hardly be persuaded to walk on them. Those who frequented these portions of the park had become so accustomed to walking on the paths and sitting on the benches that they had to be invited to walk in and sit down on the grass before they would accept what was considered such a favor. Of course, it did not take long to educate people up to their new privileges; but the fact that they had already been educated to keep off the grass is certainly worth considering. But, really, it is no greater hardship to keep on the walks in a park than it is to keep on the sidewalk and out of the front yards along the city street. The people who argue that "the parks are made to use and not to look at," may not be aware of it, but their statement is deceptive. The fallacy is exposed the moment we consider that the beauty of a park is its highest use, and, therefore, to destroy that beauty is not to use but to abuse it. When walking by a wildwood border thought-

less people often enjoy themselves by breaking off the branches of flowering Dogwood and other trees and shrubs when they are in bloom, but no sensible person would consider it an inhospitable restriction if visitors were forbidden to mutilate the shrub border of a park after this fashion. Nor is it any hardship in a park which is well planned to insist that people should keep on the gravel when a free use of the grass would destroy it, for the grass is just as essential to the beauty of a park as the shrubbery.

It is pleasant for children, both old and young, to roll on the grass at times, but this is provided for in every well-managed pleasure-ground. The large meadows in Prospect Park are thrown open most of the time, great areas in Central Park are open to the public whenever the grass will permit it, and there are days when as many as 30,000 people have special permits for picnics in Central Park, and often 100,000 people can be seen on the grass at once. It is necessary to keep the players away now and then in order that the lawns may grow green again, and there is no question, taking the season through, that there is more real enjoyment on the grass than there would be if all the turf were always thrown open to every one without restriction. It must always be borne in mind that the primary use of a city park is to rest and refresh the spirit, and for this purpose the grass and shrub borders make a strong appeal to the imagination through the eye and not through the soles of the feet. Of course, where the ratio of visitors to the number of acres is small there need be fewer restrictions, but in populous cities the supreme value of the turf is its restful beauty, and when this beauty is trampled out the park not only loses its charm, but visitors lose their respect for it and are easily induced to deface it by breaking down the shrubbery and in other ways.

The point which we wish to emphasize is that the people of New York have never felt it to be a hardship to keep off the grass, but as soon as there was an indication that this restriction was to be removed lawless persons began to destroy the shrub-borders. If this state of things should continue for a year or so, people would feel that they had quite as much right to break down shrubbery as to walk on the grass. We have been much interested in some of the so-called arguments which have been used by certain papers in Buffalo which are opposed to the building of a fence about one of the parks in that city. These papers have long articles with scare-heads, in which it is asserted that the arrogant Park Commissioners wish to keep the people out of the park and turn it into a hay-field and a nursery for shrubs, or else make it as exclusive as the private grounds of a monarch. On looking at the plan it is evident that most of these so-called arguments are based on absolute misrepresentation. The proposed fence had openings for entrance at all the leading lines of travel. Four of these entrances were made to the full width of the abutting streets, while four more were made for foot-travel. Walks were then proposed on lines which were so direct that there would have been no temptation to leave them for general travel, and we can imagine no reason for the outcry against the fence unless the abutting property-owners should have the notion that it benefits them to have the park seem to be a portion of their own private grounds. So far as we can see from the ordinances there has been no intention of the Park Board to restrict ball-playing or the usual picnic recreations in this place. A disinterested witness to whom we have written on the subject informs us that there are twenty beaten trails across this paradise-ground in every direction, and these trails are evidently not worn by people who wish to use the park as a park, but who simply want to use it as a thoroughfare, and insist on being allowed to make the shortest cut to their destination. No one considers himself oppressed because he has to turn a corner in a city instead of walking through a block. Why should it be a hardship to follow a good path when the distance is almost as short as an absolutely straight line across the grass, which will soon become a beaten track and utterly destroy its beauty?

Some time ago we had occasion to comment on the Buffalo park reports, and these newspaper articles confirm what we have said before. There is an insufficient force of park police in that city, and the people have been allowed to abuse their pleasure-grounds so long that they consider any effort to curtail their privilege to injure the parks as an infringement on their personal rights. They have kept repeating to themselves the fallacious statement that the parks belong to the people, and, therefore, the people have a right to use them, when the proposition, accurately formulated, would be this: all the people have a right to enjoy the beauty of the parks, and, therefore, a few people have a right to destroy this beauty. Fortunately, the administration of parks in other cities was begun under better auspices. In New York, Brooklyn, Boston, Chicago and San Francisco the people have been taught to appreciate their parks as parks, and nowhere except in Buffalo has any reputable organ of public opinion ventured to argue that a park is essentially an open thoroughfare. A space which people are invited to despoil is really no park in any proper sense of the word. If public opinion has become so demoralized in any city that proper regulations for maintaining the landscape beauty of their parks are denounced as tyrannous, such parks are doomed to desolation, and it would be altogether more reasonable to sell the land for building-lots than to allow it to become an eyesore.

The Live Oak at Drayton Manor.

THE illustration on page 235 is the reproduction of a photograph of what, so far as we can judge from our observations, is the most massive, symmetrical and imposing tree in eastern North America. It is a Live Oak, *Quercus Virginiana*, standing on one side of the entrance to Drayton Manor House, on the Ashley River, near Charleston, South Carolina. The home of the Drayton family, a handsome red brick Elizabethan mansion, was built while South Carolina was a British colony, and it is said that the site of the house was selected on account of this tree, although, as the Live Oak grows very rapidly, it is not impossible that it was planted with its mate on the other side of the drive, where the house was first built. At the present time the short trunk girths twenty-three feet four inches at the smallest place between the ground and the branches, which spread one hundred and twenty-three feet in one direction and one hundred and nineteen in the other. This tree is growing over a bed of phosphate, and the demands of trade will, therefore, probably cause its death before its time. More than once we have visited this tree, and each visit has increased our reverence for nature as we stood in the presence of this wonderful expression of her power.

Our illustration, for which we are indebted to Mr. Hostie, of Charleston, gives a feeble and unsatisfactory idea of this tree. Some one who sees the picture, however, may be moved to go and look at the original; and this traveler will be rewarded, for no one who has not seen the Drayton Oak can form a true idea of the majestic beauty of the Live Oak, the most beautiful of the fifty species of Oaks which grow within the borders of the United States, or of all that Nature in a supreme effort at tree-growing can produce.

The Wholesale Flower Markets of New York City.

ASIDE from the great auction flower sales held two and three times a week during spring and early summer, and the sales made by large growers to the local dealers, there are two wholesale flower markets in this city. The old-time stand on Vesey Street, abandoned to fruit and vegetable dealers some twenty-five years ago, was succeeded by the present market about the small triangular park space at the Hudson River terminus of Canal Street. When the flower growers combined to ask the city authorities for the use of this place the open tract

was a dumping-ground for cobblestones and other unsightly city belongings. Improvements were made a year or two later, and at this season the little park, with its shrubby background of flowering Wiegelia and Spiraea, makes a pleasing foil to the garden-like beds of bright flowers on its sidewalks. The second market, which is a division of the Canal Street market, began four years ago, and is better known to the public from its more central location. It occupies the wide street space on the north side of Union Square. In the misty morning twilight, the tall modern business and publishing houses, grim and silent, make a striking contrast to the bustle of flower-selling in the street, and their broken and irregular sky-line suggests the medieval and scarcely more picturesque house-tops of the buildings about a market place in the heart of an old European city.

Of these flower markets very little is known by the public, for even the universal enjoyment afforded by great masses of gay flowering plants, or the interest in the displays for their business or commercial value, is not sufficient to bring out visitors to the early sales. During the evening, flower-laden wagons start from the suburbs of Jersey City, from West Hoboken, Staten Island and Long Island, and by midnight the earliest comers have secured first choice of location, the same place being held throughout the season, if possible. The two markets differ but little in the conduct of the sales. At the more central stand, then, the black-covered wagons are headed to the curbs. They are closely packed, the floor, two tiers, and even the top increasing the carrying space. The noisy rumble of the vehicles, as they come one by one, makes part of the roar of early morning traffic, along with belated trucks of jingling milk cans and the newspaper delivery wagons hurrying to railroad stations. Unlike the occasional early riser, who thinks bustle and noise a necessary part of his unusual experience, and that folks who are not awake should be, the men, wakeful and alert, noiselessly chat in pairs on the front seats or stand about in groups, the midnight darkness relieved by electric lights. Within Union Square the benches are closely occupied by men who sit through the night, the humane police officer explaining that they are allowed to wait on the seats provided they do not sleep.

By three o'clock the activity and noise of arrivals is at its height, and the busiest streets of many towns at mid-day is outrivaled. Along with the latest loaded wagons of the sellers come the first empty ones of buyers, and these find places on the outskirts. Suddenly a movement extends along the closely ranged line; men, women and here and there a sleepy-looking child hurriedly move wooden trays filled with plants to the street space at the rear of their wagons, until the long block is lined with two solid rows of flowers fifteen or twenty feet wide, separated along the middle by an open walk twelve feet broad. By half-past three shrewd experienced men and women—the latter generally short-skirted and blue-aproned Germans—are peering through partial light and into deep shadows in search of bargains and choice stock. Only two Italian venders were noticed among the many customers. These advance buyers are peddlers, owners of the low-sided, open empty wagons, and eager to get stock, which is quickly arranged at the end of the lines, in readiness to offer to buyers in small lots at a slight advance. Later in the day the remaining stock of these middle dealers is sold in the tenement sections of the city and in the suburbs along the Harlem and Hudson and in New Jersey towns as far as twenty miles away. Some of the early buyers come to secure plants ordered by them in advance for customers who have engaged a special sort, and occasionally there is eager rivalry and the excited claim that certain stock has been "bestellt." Sturdy, thrifty women carry away their purchases in large, flat baskets, one on each arm, while a few push carts start off with their meagre stock. One or two immense vans belonging to high-class florists are closely packed with choice stock, bought up by

a member of the firm. These roomy vans are especially built for this trade, and besides double walls have heating and ventilating arrangements against any possible cold which might chill tender plants. The ordinary open wagons with low sides are filled with stock selected with a view to the best plants for the least money and the showiest effect in the general arrangement. Feathery Astilbes make a graceful temporary edging to beds of brilliant flowers, five or six dozen Geraniums going into each load. The front step, an improvised platform at the rear and extensions at the sides are all pressed into use. The only lull in the activity after midnight is the half-hour before five o'clock, when the regular trade of store-keepers, street-venders and peddlers is awaited. By six o'clock retail buyers begin to pass up and down the long array of flowers and to buy single plants of different sorts, the pots clumsily wrapped in newspaper, and an artist making a water-color sketch of the gay scene gets more notice than is helpful. By half-past eight the fee of twenty-five cents for each wagon has been collected by a deputy from the Bureau of Markets, the wagons have left, and cleaners from the Park Department have removed all trace of discarded plants and broken pots.

The flower markets begin early in April, when three or four wagon-loads are offered in the damp and chilly dawn. The trade gradually grows, and by the first of May thirty wagons are assembled at each market every morning, Saturday being the busiest day. Now and until the close of the season, about July 1st, as many as seventy-five loads will be disposed of daily at the two places. A moderate load contains 40 to 50 trays, and these each hold one or two dozen plants, so that a large wagon may carry 2,000 plants. One dealer, together with an assorted stock, offered of Verbenas alone 1,000 plants in boxes holding a dozen. Easter Saturday and the morning preceding Decoration Day are the big days of the season, when it is not unusual for one grower to send in two or three wagon-loads instead of one. The plants must be well grown and in luxuriant flowering, since each one is finally subjected to selection by a retail buyer for a place in the window or door-yard. Geraniums are the most popular, as the showiest, most persistent in bloom and the easiest grown, and they continue in demand from the opening to the closing day. Boxes of deep orange-colored Calendulas, with the smaller-flowered yellow Daisies, *Anthemis tinctoria*, are among the showiest effects, and hardly less bright are masses of Nasturtiums of assorted colors, patches of Marigolds and of Lantanias. Lady Washington Pelargoniums make an effective show and win many buyers, while Fuchsias covered with heavy buds and the blue Corn Flower of their grain-fields are in especial favor for retail sales to German householders. Old-fashioned plants, as Bachelor's Buttons, Cockscomb, Old Man, Scarlet Sage and Musk-plant have a steady demand, and creepers and climbers, as Stone-crop, Ice-plant, Myrtle, Creeping Charlie, Vinca and Tradescantia, are shown in quantities. Memories of house plants familiar to a far-removed childhood, of almost forgotten country gardens, and of haunts by shady brook-sides are called up by plants of Lemon-verbenas, Lobelia, Oleander, House-leeks, Phlox, Cigar-plant, Ten-weeks'-stocks, Thrift, Sweet William, Zinnias, Forget-me-nots and Ferns. Trays of vegetable plants are also among the offerings, 120 plants of tomatoes selling for thirty-five cents. Other prices at this season are a dozen and a half Zinnias for one dollar, while the same sum will buy thirty-five flowering Verbenas, a dozen good Geraniums, two or three boxes of Pansies according to quality, each holding thirty plants, two dozen Musk-plants, twelve large plants of Vinca, or two dozen Pyrethrums or Armerias. Roses of all varieties and grades and Hydrangeas are abundant and generally well grown and stocky, though some plants are leggy. In the Easter season, Lilies, Azaleas, Hydrangeas and Cytisus are the principal offerings. Bulbous plants are comparatively rare. At the Canal Street market the trade

is in bedding-plants and entirely wholesale, while at Union Square many decorative plants of large size are seen, such as Portugal Laurels, Palms, Rubber-plants, and Arbor-vite sheared into various shapes. More stock is being offered each year, and prices this season have been lower than in former years. The growers estimate that it costs a dollar to grow a dozen Geraniums, while ordinary stock brings only seventy-five cents. Plants of Geraniums must be very good to command \$1.25, and the choicest stock noticed, extra-large, full-flowered plants of the variety General Grant, brought \$2.00 a dozen.

The market season is over by the end of June. The cultivators then occupy themselves in repairing greenhouses, growing on stock for fall and winter cuttings, and in caring for their bulbs of Easter Lilies from Bermuda and Rose stocks from Belgium. The winter is given up to anxious care and cultivation for the spring rush, which rounds out the year. Altogether, it is hard work, which yields not more than a fair living and often but a frugal one. Cold days and stormy weather operate against sales, and large receipts of strawberries and other fruits take the hucksters into other lines of trade and make slow sales and low prices in the flower markets. Dull market days are often helped out by buyers from Springfield, New Haven and other towns in near-by states, who can buy more cheaply in the metropolitan markets, even when the cost of transportation by water or rail is included.

It is not possible to give an approximate idea of the total sales in these markets for a season, but the flower trade has assumed great importance since the beginning of the century, when there was but one commercial florist in the United States. There are now nearly 5,000 establishments for growing flowers, and four-fifths of this business has been developed within the last twenty-five years. The last census report states, among other interesting items connected with floriculture, that 38,823,247 square feet of glass are in use, covering more than 891 acres. Of these establishments, 312 are owned and conducted by women. The value of fixtures, heating apparatus and tools amounted to \$40,000,000. Fuel, freight and express, and postage on some 20,000,000 catalogues are other large items of expense. The receipts from sales of cut flowers are put at more than \$14,000,000 a year, and from plants and shrubs at above \$12,000,000.

The Temple Show.

THE annual exhibition of the Royal Horticultural Society, which was held this week in the Temple Gardens on the Thames Embankment, proved a success in every respect. The weather was on its best behavior, the exhibits were of a high order of merit, and the crowds of visitors which thronged the lawns and the five large marqueses on each of the three days could not fail to satisfy the financial secretary of the exhibition. Compared with previous exhibitions of the same kind, the present one excelled in the more tasteful arrangement of the plants, flowers, etc., and in the quality of the pot-grown specimen Roses. Orchids were as numerously represented as ever, but there were fewer large specimens and much fewer novelties among them. This probably was due to the fact that a large international horticultural exhibition was being held at the same time in Paris, and this necessitated a division of the forces of some of our most powerful exhibitors. Notwithstanding these slight drawbacks, however, the show was a magnificent display of high-class horticulture, such as Englishmen might justly feel proud of. The Roses were magnificent and quite justified the observation of a lady which I overheard: "Among all the beautiful and wonderful things here to-day the Rose stands supreme."

CRIMSON RAMBLER attracted a large share of attention, beautiful specimens a yard across, bushes as well as standards, in pots, of course, and covered with large clusters of brilliant carmine-red flowers, each one and a half inches

across, semi-double, elegant and charming, both in bud and when fully expanded. I counted twenty and more open flowers on each of many of the clusters. Another new Rose of great promise is Paul's Carmine Pillar, of which fine examples were shown. The flowers are borne singly on the ends of the branches, each flower being a cup nearly five inches across, quite single and of a rich rose-crimson color, with a large white eye. It was shown by G. Paul & Son. Another attractive Rose was a new one of last year, named Duke of York, a China bedder and winter flowerer. Messrs. W. Paul & Son showed specimens of it in pots, which were flowering for the second time this year, the flowers being clustered, small, but pretty, both in bud and when expanded, their color a bright rose-crimson.

Among the many Rhododendrons shown, the most beautiful by far was the Mollis hybrid named Anthony Koster, the trusses being large and crowded, the flowers Mollis-like in substance and form, and the color a glistening lemon-yellow. There are hundreds of Ghent and Mollis Azaleas in flower at Kew now, but not one that is so pleasing in all respects as this. It was shown by Messrs. J. Veitch & Sons. Magnolia Watsoni is not first-class as a pot-plant, at any rate as shown by Messrs. Veitch. The reverse may be said of the pretty hybrid shrubby Spiraea named Van Houttei, which was shown in pots as bushes a yard through and covered with elegant wands of May-like flowers. It is the best of the Spireas in flower in the open at Kew now. It is a hybrid between *S. trilobata* and another, probably *S. confusa*, and is often met with in gardens under the latter name.

LILAC, SOUVENIR DE L. SPÄTH, was the best of all the varieties of Lilac shown, its enormous racemes of large plum-purple flowers being very much admired. The best of the white varieties was Marie Legraye. New varieties of Tree Peony, from Messrs. Kelway, of Langport, whose exhibit of hardy plants generally was a great attraction; some splendid specimens of Streptosolen Jamesoni, from Mr. Bennett-Poë, and a collection of fifty-six varieties of Darwin Tulips, from Messrs. J. Veitch & Sons, were among the most noteworthy of the exhibits of hardy plants.

CLERODENDRON A'PRIORI, a variety of Clerodendron Balfouri, with flecks of red in the white calyx, is likely to find favor as a novelty with growers of stove climbers. Messrs. Veitch's seedling Phyllocacti are an advance upon what we have had hitherto among this beautiful but neglected section of Cacti. Their improved races of Streptocarpus are equally progressive, new colors as well as new shapes being observable among the large number of seedlings shown this year. What they call *S. gratus*, however, is nothing but *S. Watsoni* showing greater variety of color. These are remarkable for their large clusters of flowers and their large somewhat "floppy" leaves.

CLEMATIS.—Messrs. G. Jackman & Son showed a set of six varieties of the new hybrid Clematis, raised from *C. coccinea* and a large-flowered variety named Star of India. I noted one of them last year when the variety named Countess of Onslow was awarded a first-class certificate by the Royal Horticultural Society. The other five are Duchess of York, pink; Duchess of Albany, rosy mauve; Grace Darling, mauve; Sir Trevor Lawrence, crimson, and Crimson Beauty, deep red, with a purplish shade. The flowers of all these have the petals arranged so as to be almost tubular at the base, and they are thick and fleshy, as in *C. coccinea*, but twice or thrice as large. Messrs. R. Smith & Sons again showed a grand group of specimens of the large-flowered Clematis, which, if not quite equal to those shown last year, were yet of such quality as to excite admiration, if not envy.

MILTONOPSIS BLEUII VIRGINALIS would be better—that is, more correctly—designated if called Miltonia vexillaria virginalis. Whatever its origin, it is simply a white-flowered form of the last-named, a superb one, truly, but bearing no evidences of its reputed hybrid origin. It was shown by Monsieur Charles Vuysteke, of Belgium, and obtained a first-class certificate. The flowers were four inches across,

pure white, save a small dash of rose-purple at the base of the petals and a star-like blotch of pale brown at the base of the lip.

EPIDENDRUM STAMFORDIANUM was shown in magnificent condition by Sir Trevor Lawrence, a big plant bearing about a dozen strong branching spikes of bloom, springing from the bases, and not from the apices of the pseudo-bulbs, a character peculiar to this one species in the large genus Epidendrum. The flowers are colored pale yellow and red, and are fragrant. Masdevallia nycterina was shown by Baron Schröder with three hundred flowers arranged round the bases of the leaves like a collar. It was a fine example of cultural skill. The beautiful Cattleya Hippolyta was shown by Monsieur Hye-Leysen with a spike two feet high bearing eight flowers. Miltonia Phalaenopsis, Princess of Wales, a remarkable variety, with the lip almost wholly crimson, was shown by Messrs. F. Sander & Co.

CYPRIPELIDIUM STONEI PLATYTÆNIUM was represented by a fine plant bearing two scapes, each with two flowers. It is said to be the largest of the very few plants of this rarity known to be in cultivation, and the price it was valued at by dealers was eight hundred guineas! It was awarded a first-class certificate, a superfluous distinction in this case.

The group of new stove and greenhouse plants exhibited by Messrs. F. Sander & Co. contained fine specimens of their Dracæna Sanderiana, D. Godseffiana (awarded a first-class certificate), Heliconia illustris rubricaulis, Ludovia crenifolia, Begonia Rajah, Sarracenia, Darlingtonia, Ari-sæma fimbriata, etc.

Altogether there was a marked absence of really new and striking plants this year, compared with other years. I think connoisseurs were attracted most by an indifferently flowered plant of Incarvillea Delavayi, shown by Sir Trevor Lawrence, I believe, for the first time in England, although well known to Continental growers. It received a first-class certificate.

LESCHEAULTIA BILOBA MAJOR.—A large group of this beautiful blue-flowered Australian shrub was shown by Messrs. Balchin, of Hassocks, in Sussex, now famous for the cultivation of this and other rare greenhouse plants. Nothing could be more effective among blue-flowered plants than this Leschenaultia as grown at Hassocks, and few plants are more deplorable than it is when grown with the ordinary greenhouse collection. We cannot grow a presentable specimen of it at Kew.

Ivy-leaved Pelargoniums were exceptionally good as shown by Mr. Jones, of the Ryecroft Nurseries, the plants being dwarf and crowded with flowers, all double, and of every shade of color between white and crimson. Show Pelargoniums were also well represented by groups of large specimens from Mr. Jones and Mr. Charles Turner, of Slough. The plants from the latter establishment were fully a yard across, and profusely flowered as only Mr. Turner knows how to flower them.

Messrs. T. Rivers & Sons, of Sawbridgeworth, maintained their great reputation as cultivators of exhibition fruit by contributing a group of Nectarines grown in twelve-inch pots, each plant being about four feet high, covered with fine healthy leaves and bearing about twenty large beautifully finished fruits. This exhibit deservedly won the only gold medal awarded.

There were great collections of fruit of all kinds, vegetables, herbaceous plants, Ferns, Caladiums, Pansies, Begonias; in fact, of every class of plant that finds favor with cultivators, and all first-class. The Roses were, however, the feature of the exhibition.

London.

Plant Notes.

IRIS MACRANTHA.—This Iris, introduced by Max Leichtlin two years since, is an *I. Germanica* with very broad foliage and very bold flowers of the largest size, superior in the latter respect to any Iris yet introduced. It is, of course, a bearded Iris, and the large standards are light blue-purple,

the falls are richly colored and somewhat vinous-purple in tone. The plant is of medium stature. This variety differs little from the German Iris from Amasia, which has been noted in these columns as a bold flower.

IRIS PALLIDA, var. *DALMATICA*.—Among Irises this variety, long since introduced into cultivation, stands prominently as one of the best for the garden. It is a plant of vigorous, free-growing habit, with bold leaves, and flowering-stems nearly four feet tall. The dark lavender flowers are of fine form and highly perfumed, reminding one of the Locust-flowers. In flower this plant has an air of great distinction as well as beauty. There are many hybrids of *I. pallida* among the German hybrids, usually easily recognized by their thin withered spathe valves. One of the best of these hybrids is Madame Elmira (Woolson), whose flowers are not as bold as those of the Dalmatian type, but are of a much lighter lavender color, and also well perfumed.

PYRETHRUM PARTHENIFOLIUM.—There are no flowers more popular than the Daisies, albeit they are not specially appreciated by the farmers. No composites will probably ever supplant white Daisies in the affections of the public, but in cultivation or the garden the colored Daisies, or Pyrethrums, prove universally acceptable. The plants are reliably hardy, and their handsomely cut foliage is very attractive. They flower very freely in a wide range of color, generally from the faintest flesh shade to a brilliant crimson. Florists have produced many double-flowered forms, which somewhat resemble Anemone-blooms, but the most graceful ones are single, which are decidedly less heavy in effect and better in color. A good range of colorings may usually be had from a packet of seed, to be had of most seedsmen.

VINETOXICUM ACUMINATUM.—This plant, often called the Mosquito-catcher, should have a place in every collection of herbaceous plants, as it is one of the showiest things at this time of the year and remains in bloom several weeks. The flowers are star-shaped, creamy white, in short cymes, generally springing out of the sides of the stems between the leaves, and not from the axils, where most flowers are produced. It would seem to be a climber in its native habitat, as the stems have a manner of growing as if accustomed to twine on contiguous herbage, but they do not seem to mind the want of support in the least, and the plants look all the prettier without it. Propagation is easiest effected from seed, of which the plants produce a plentiful supply; cuttings of the ripe wood will root if put in a humid atmosphere. The flowers of this species secrete a viscid substance and catch insects much in the same manner as the "Cruel-plant," *Physianthus albens*. They both belong to the Milkweed family, along with such plants as the Stephanotis, Hoya and the like.

Cultural Department.

The Russian Tree Fruits in America.—II.

THE fact that I took up my abode among the hills of northeastern Vermont, and the added fact that from boyhood I had been an ardent lover of horticulture, and especially of fruit-growing, led me of necessity to search for such varieties as would endure the almost Arctic severity of that section of New England. The first five years were given to the trial of what were regarded and recorded as the most hardy sorts far north. But I very soon discovered that altitude was an even more important factor than latitude. In Bangor, Maine, on exactly the same parallel (forty-five degrees, N.), many of the standard Apples and Pears can be grown; while on Lake Memphremagog not one single tree on the list could be relied upon, and, in fact, none of them ever did, in my grounds, reach bearing age. Varieties grown about Montreal were also entire failures, from the same cause.

My attention was then turned to a search for native varieties. Along most of the well-traveled roads there was no lack of Apple-trees capable of resisting the climate; but all, so far as I could learn, were of very poor quality and small size. Gradually, as I became more familiar with the country and the people, I was able to learn of farmers who had a few

Apple-trees producing fairly good fruit and capable of resisting the climate; but I did not find then, nor have I since noted, a single instance of such fruit being increased by grafting or budding, these simple arts being seemingly quite unknown. Continually on the alert for anything of the kind, I have now, after thirty years' residence, been able to find among our people only three native Apples of any commercial value. One of these, Scott's Winter, is now grown all through the "Cold North," from Maine to Minnesota, and is generally regarded as one of the best native long-keeping ironclads. The others, Magog Red Streak and Newport Winter Sweet, have a local reputation and are considerably grown.

The importations of Russian varieties plainly demonstrated that there was a race of Apples which would resist our severest climate and thrive. But here again disappointment awaited us; for not one of the hundreds of varieties which were imported proved to be a long keeper in our climate. Grown in Russia, up to six hundred miles farther north than our northern boundary, they might—at least some of them—be good keepers at home; but in the northern tier of American states, and even in the Canadian provinces, they all proved themselves, however otherwise acceptab'e, to be deficient in keeping qualities for winter. And this continues to be true to-day, with few and rare exceptions, not only for the imported trees, but for nearly all seedlings grown from them, or from crosses on our older varieties of native origin. Up to date it may be said that fine in size, quality and beauty as are many of these Russian tree fruits, not many of them are reported which are at once good winter keepers and fully possessed of other required market qualities. We are anxiously waiting for such to appear, and all growers will hail their advent with real gratitude.

Shall we Irrigate Orchards in New York?

IN the current discussions of fertility of the land, nearly the entire emphasis is placed upon the importance of supplying nitrogen, phosphoric acid and potash; but I am convinced that it is quite as often necessary to enlarge upon the importance of water. It is well known that all arable soils contain much more plant-food than any crop, or even any twenty or more crops, can use. The chief aim of tillage is to render the greatest amount of these materials available to plants. In order that they may become useful to crops, these materials must enter into solution in water; and, all other conditions being favorable, the more water the soil has the more plants will grow. In very many cases, an application of water is much more advantageous than an application of fertilizer. This is well shown in many of the arid lands of the west, where a small amount of irrigation renders the soils wonderfully productive.

Just how much, if any, water can be added to agricultural lands in the east with profit, must be answered for each individual instance; but for orchard lands it is a question if, in general, irrigation can be profitable. We must first determine if fruit-trees can profitably use more water than normally falls in the rains. There are two ways of attempting a solution of this complex question. We might attempt to make an estimate of the amount of moisture evaporated by an orchard and then compare this amount with the rainfall; or we might observe the experiences of careful orchardists extending over a series of years. There are so many uncertainties in the former method that one is forced, in a practical discussion, to rely mostly upon experience and upon general considerations respecting plant-life. In the first place, it is to be observed that there have been no careful experiments upon a comprehensive scale in irrigating orchards in the east, and we are obliged to draw our illustrations from experiences in irrigating annual crops. Practically, all these experiences show that irrigation is capable of greatly increasing the yield, and this, too, when the natural rainfall has been well conserved. Whether the added yields are ever or always worth the extra cost, is a question which need not be considered here; the important point to be noticed is that the land is capable of giving a larger product than the average rainfall will allow.

But does this conclusion apply equally well to orchards? In this case we generally do not need more growth, but more fruit; and it is plain that if a tree is capable of bearing as many good fruits as the branches will hold with the normal rainfall, it would be folly to apply more water. We all know that the well-tilled orchard is capable of doing this. It was done in numerous cases in the drought of last year in New York state, even when there was no attempt to conserve moisture. Irrigation would unquestionably give us more growth, and consequently larger trees; but it is very doubtful if this would

mean greater profit. And in drawing observations from the effects of irrigation upon annual crops, we should remember that the roots of such crops are near the surface, while those of trees spread far and deep.

The fact is that we are now wasting a large fraction of our annual rainfall, and it is useless to talk of irrigation until people have arrived at the point of saving the water which nature gives them. The average annual rainfall of New York varies in the different parts from about thirty-five to over fifty inches—that is, nature spreads a sheet of water three to four feet deep over our lands every twelvemonth. Much of this falls in winter and very early spring, to be sure, but even this portion of it may be saved to a much greater extent than most persons are aware. I venture the assertion that if the cultivator were to do his utmost to save this great benediction of the heavens, not only the orchards, but most other crops in New York state, could not be irrigated with profit. It is not my purpose to discuss the methods of conservation of moisture at this time. They have been explained over and over again. They consist, essentially, in mulching the land with a shallow layer—generally a dry one—of surface-soil; in plowing very early in the spring before the soil-moisture has been lost into the atmosphere; in covering the land with herbage in fall and winter, and, in the case of cover crops, of plowing them under at the earliest moment in spring, before they have evaporated much moisture from the soil.

There is another point respecting the utility of soil-moisture which should not be overlooked. Very many of our lands contain as much available plant-food as the average soil-moisture can utilize. In such soils it is idle to apply more plant-food without applying more water at the same time, or, to state the case differently, without improving the methods of cultivation so as to save the greatest possible amount of the rainfall. The drought of last year cut short the growth of much nursery-stock in western New York, and nurserymen are now asking if they should not have applied nitrate of soda, or some other commercial form of nitrogen. The probability is that such applications would have been of no avail unless the tillage had been improved at the same time; and it is a question if tillage alone, if it were begun early before much of the soil-moisture had been lost, would not have given the desired results. At all events, it is certain that the effect of much of the fertilizing of land is lost because the tillage is not improved, and the greater the outlay in the application of commercial plant-food, the greater should be the attention to tillage and conservation of moisture.

If all these considerations are well taken, it is evident that, instead of recommending irrigation, we should urge the saving of the water which we already possess. When any person has done his best in this direction he is in position to consider the feasibility of applying water artificially to his lands.

Cornell University.

Mexican Water-lilies.

THESE species are worthy of special mention, being among the most attractive and deserving of general cultivation. All lovers of aquatic plants, botanists and others, are indebted to Mr. C. G. Pringle and other collectors, who have of late years brought these Water-lilies again to notice. Five years ago I received a root of the species *Nymphaea Mexicana* for trial. This proved far superior to the well-known *N. flava*, although it is almost identical in form, size and color. Its flowering habit compared favorably with any of the free-flowering varieties, while it is well known that *N. flava*, under cultivation, is the shyest bloomer and most unsatisfactory of any. *N. elegans*, a most charming species, was also received from the same source. It is a moderate grower and well adapted for cultivation in tubs, small basins, etc. *N. gracilis*, of recent introduction, is one of the most desirable kinds in cultivation. It is the only tropical species with white flowers which blooms in the daytime. These flowers are of the Stellate type and stand well above the water. The rich, golden yellow stamens and the delicate fragrance are the characteristics of this variety.

The new blue Water-lily, as figured and described in GARDEN AND FOREST, May 22d, page 205, is entirely distinct from any other blue Water-lily in cultivation, and corresponds with one I have raised from seed, received from the same source as *Nymphaea gracilis*. The plant resembles *N. gracilis*, while the flowers are much larger, with the same long-pointed buds. The flowers open early in the day and remain open longer than those of the Zanzibar species. They are borne on stout peduncles and stand well out of the water. The leaves have long petioles, as if they grew naturally in deep

water. They are light green above, with a few blotches, and of a dark purple beneath. One striking feature of the stock of this blue Lily is that it produces no seed, consequently it is difficult to propagate. At the same time, it is a most profuse bloomer. Another good feature is that strong-growing plants will ripen a tuber that can be preserved with more certainty than those of the Zanzibar type, when large flowering plants have been grown the previous season.

Clifton, N. J.

W. Tricker.

Cladrastis tinctoria, the Yellow-wood, is bearing an extraordinary heavy crop of flowers this season. It is one of the most beautiful of the low-growing trees when in flower, and yet in Washington, the home of trees, it is doubtful if there are more than half a dozen examples of it in the city and surroundings. There are two magnificent specimens of it in the Capitol grounds, which have much larger racemes of flowers than we usually see, the one growing on the slope to the south of the Capitol having racemes fully twenty-four inches long. The flowers do not last more than a fortnight, and if the weather is warm their life is shorter still, but the tree is attractive all the season through. It is hardy up to the Canada line, and grows rapidly. The gray bark is of fine texture, and this, with its pleasing ramification, makes it a beautiful object in winter. It has graceful light-colored foliage, which remains late and turns to a clear yellow in autumn. Its one drawback is the brittleness of its wood, which makes its branches liable to break.

Papaver orientale.—The Oriental Poppies last but a short time in flower, but they are well worth the care bestowed on them even to have them in flower for only a week or so during the year. The flowers are in some cases as large as eight inches across, the petals of a bright fiery or orange red, but out of a batch of seedlings we get quite a number of flowers approaching scarlet. This Poppy, being a perennial, can be increased by root division, which is, at the best, a slow and uncertain method of propagation. To have it in quantity the best way is to sow the seed early in the fall in good-sized boxes, where it will soon germinate, and with the protection of a cool frame the seedlings can be left in the box all winter, and by spring they should be potted off into three-inch pots. As soon as they have developed a few good-sized leaves they can be planted out in their permanent positions, where they will flower the following spring. The variety *bracteata* is only a slight variation from the type, having large bracts under the petals; the flowers are lighter in color than those of *Papaver orientale*. A dwarf form of *P. orientale*, called *Triumphans*, has the merit of being very floriferous.

Correspondence.

Notes from Brookline, Massachusetts.

To the Editor of GARDEN AND FOREST:

Sir,—There is now on view a grand display of Indian Azaleas in the home garden of Professor Sargent, in Brookline, Massachusetts. Every plant is a perfect specimen, showing a high state of cultivation. Some are globe-shaped, balloon, pyramidal, besides many irregular, but graceful, forms, and all a mass of bloom. There is almost too much color, and, as the gardener remarked, pointing to one or two plants showing a little green foliage, more foliage would help relieve the eye, and tend to a better appreciation of the various contrasting colors. The collection is made up exclusively of single-flowered varieties. Single flowers of graceful outline like the Azalea, especially those of the Indian type, are more refined, and certainly far more effective, than double flowers of this plant could possibly be. One other reason why single flowers should have preference is that the production of double flowers is a greater strain on the plant, and, as a consequence, they cannot be relied upon to bloom well every season, and the plants are never as massive as those of the single forms.

These Azaleas are cultivated on the European plan—perhaps, more correctly, the Belgian—modified according to the different climatic conditions. Here they are planted in the full sunlight. To many gardeners, with the English pot system of cultivation in mind—and shade, even in England, is considered essential—it appears a bold plan, and it is hard to persuade them to give it even a trial. Nothing succeeds like success, and here is the evidence. A full account of the method of cultivation followed here is given in GARDEN AND FOREST, vol. vii., No. 354.

Among several striking varieties were *Roseum magnum*, a showy flower of beautiful vermilion; *Daphne*, a beautiful

white, one of the finest; Roi d'Hollande, deep red, brilliant in tone; Etendard de Flandres, cerise-pink, a very large flower, with wavy edges; Duc de Nassau, salmon-pink, large flower, very effective; Dame Mellain, blush, with a deeper blotch; Eulalie Van Geert, charming blush; Madame Verschaffelt, crimson blotch on light pink ground; Iveryana, old, but an excellent white variety with pink stripes.

Stored with the Azaleas last autumn, in deep glass-covered pits, unheated, and with no protection beyond the ordinary covering of shutters, were several large plants of the lovely greenhouse climber, *Trachelospermum jasminoides*. They are trained on wire, column fashion. These are all remarkable specimens, some of them eight feet tall and literally covered with pendent cymose panicles of sweet-scented white flowers. There is abundant shiny, deep green foliage, and the plants are so neatly and skillfully trained as not to show the least trace of the wire framework. They are in tubs, which are replaced for larger ones in every three or four years, and manure-water is supplied during the growing season.

It was a treat to me to see the Glory Pea of Australia, *Clinanthus Dampieri*, in bloom for the first time. It is considered quite an achievement to bring a plant along so far. The flowers are vinous-red, with a dark, almost black blotch, at the base of the standard. The species is herbaceous, and is generally raised from seeds sown in small pots in the autumn and held over until the next season, when they are expected to bloom. If sown in spring they might attain a fair size, but would not bloom by autumn, and the chances would be considerably against saving them through the winter. Those who have succeeded with this plant never water it directly in the pot it is growing in, but have the pot plunged in some material which is watered.

Conspicuous on the grounds was a fine tree of *Pyrus coranaria* in full bloom. No one who sees this handsome tree and enjoys its delicious perfume will ever forget it. Its odor is most penetrating, being appreciable fifty yards away, and so acute that I was unable, after passing the *Pyrus*, to realize the slightest trace of perfume from near-by bushes of the well-known aromatic *Calycanthus floridus*.

On the rock-garden is an interesting lot of plants, but my time being limited, I could only note a group of *Primula cortusoides*, very effective in pink shades, and *Verbascum phoenicium*, in purple and white, which made a most striking show.

The drive-ways and shrubberies of the Arnold Arboretum, at Jamaica Plain, are thronged with visitors every fine day. The splendid collection of Garden Lilacs, of which there are more than a hundred varieties, is a great attraction, and judging from the way note-books are brought into use, it is safe to assume any nurseryman near Boston who has a good stock of these Lilacs will do a good business. I noted Ludwig Späth, deep purple-red, large flowers; Philemon, dark purple, very fine; Alphonse Lavallée, deep blue; Virginité, double, rose-tinted in bud, violet when open, sweet-scented and evidently a great favorite; Monsieur Jules Finger, rose-colored, very fragrant; President Massart, reddish purple, very large; Renoncule, double blue, fragrant; Marie Le Graye, showy white.

Wellesley, Mass.

Trees and Shrubs at Madison, Wisconsin.

To the Editor of GARDEN AND FOREST :

Sir,—The climate of the north-west is a trying one for many trees and shrubs which are at home on the Atlantic seaboard, and I send a few notes on the hardiness of certain species tested here. Engelmann's Spruce, *Picea Engelmanni*, generally shows the effects of the winter a little on the south-west side—at least in young trees—by the browning of the tips of the younger shoots. This defect is not sufficiently marked to destroy the symmetry of the tree, nor to prevent its being one of our most beautiful lawn trees. *Abies concolor* has proved less hardy, young trees having suffered quite seriously from winter-killing. Even the White Pine, *Pinus Strobus*, sometimes shows the effects of the winter a little in young trees by the browning of the foliage on the south-west side. The Colorado Spruce, *Picea pungens*, and the Douglas Spruce, *Pseudotsuga taxifolia*, endure the winters without perceptible harm, though the young growth of both received quite a setback by the recent frosts.

Eleagnus longipes is not hardy here unless protected. During the winter of 1893-1894 unprotected plants showed little injury to the wood, but the flower-buds were destroyed, as was shown by the fact that protected plants bore fruit luxuriantly while unprotected plants of the same age gave none. During the past winter unprotected plants were killed to the

snow-line, while beneath this line the same plants are not only alive, but have bloomed profusely. The large-flowered Hydrangea, *H. paniculata grandiflora*, endures our winters without perceptible harm, but unless well-watered through our long summer droughts the flower-clusters are so small and develop so unevenly that they have little beauty.

The purple-leaf Plum, *Prunus Pissardi*, has proved unable to endure our winters. Teas' Weeping Mulberry seems entirely hardy with us and forms an attractive lawn tree. The weeping Mountain Ash, however, has suffered badly from sun-scald on the south-west side. The Camperdown Elm seems entirely hardy, and the Kilmarnock Weeping Willow, in sheltered locations, endures the winter with little harm.

The Amoor Tamarisk, *Tamarix Amurensis*, is not at home in Wisconsin. The young growth kills back more or less every winter, and in the winter just past it suffered more than usual. A variety of *Rosa rugosa*, from Russia, obtained from the Iowa Agricultural College, has thus far proved hardy without protection. Its large, deep rose-colored, single flowers appear profusely in June, and occasionally afterward, and are very attractive. This Rose will surely become popular in climates where few other varieties can be grown without protection.

The Yellow-wood, *Cladrastis lutea*, is hardy in sheltered locations, as are also the Maiden-hair Tree, the Gingko and the White Fringe tree, *Chionanthus Virginica*.

Deutzia gracilis kills to the ground every winter unless protected; in spite of a covering of earth it received serious damage last winter. Three species of *Caragana*, received from the Iowa Agricultural College, appear entirely hardy. These shrubs are attractive and popular. The foliage is pleasing, and their yellow pea-shaped flowers appear in May. The Japan Ivy, *Ampelopsis tricuspidata*, while not hardy in exposed situations, is not a complete failure when planted on the east or north walls of buildings. In the past severe winter vines thus planted suffered little.

An Enemy of the Larch on the High Alps.

To the Editor of GARDEN AND FOREST :

Sir,—The ravages of *Steganoptycha pinicolana*, Zell, in the forests of Larch, *Larix Europea*, on the high Swiss Alps, is the subject of an important monograph by M. I. Coax, Inspector-General of the forests of the Swiss Confederation. This paper is illustrated by a colored plate representing the insect in its different stages of development, the branches of conifers attacked by it and the principal enemy of the pest, which is a fly of the genus *Tachina*. The work is further enriched by a well-executed map of the Engadine, showing the afflicted area in different years.

From time to time the forests of Larch of the high Alps in Valais, Engadine, Dauphiny and Tyrol have been invaded by this little butterfly, the injuries inflicted by it being in proportion, as the forests consist more or less exclusively of Larch. All the adult Larch-trees are affected by the larvæ of the *Steganoptycha*, which appear in spring, and at the end of a few weeks the leaves are eaten or entirely skeletonized. The forest then offers in summer a deplorable appearance; its verdure completely disappears; the trees present a uniform reddish brown appearance, and are more or less covered with little caterpillars, which descend from one branch to another by means of threads sometimes several meters long. During the months of July and August the caterpillars are transformed into chrysalis, and at the end of ten or eleven days the little gray butterflies emerge and cover the branches of the trees with their eggs.

The damages which these insects cause are not immediately apparent. The following year the trees clothe themselves again with leaves and continue to vegetate, but if the ravages of the insect are renewed during several consecutive seasons the forest suffers severely; old trees die, and the existence of even the most vigorous is threatened, for at elevations of from five to six thousand feet above the ocean in the Alps, where plant-food is scarce and the climate is exceedingly rigorous, little is needed to weaken the vitality of trees.

It is practically useless to try to destroy artificially these minute insects, innumerable in numbers. They can only be kept in check by indirect methods, such as the effective protection of insectivorous birds and the mixing of other species of trees with the Larches in the forest. It is only the pure forests of Larch that are exposed to destruction by the attacks of the *Steganoptycha*, which requires for its existence the light found in forests of Larch, which cast very little shade. In the dense shade and humidity which exist in forests of

evergreen Conifers this insect cannot live. And if its larvæ attack isolated Larch-trees in a mixed forest, which is exceptional, the damage is not great, the space left by a dead Larch being soon filled by neighboring trees. M. Coax therefore proposes, in order to save the forests of our high Alps, to plant everywhere in the regions exposed as many trees of *Pinus Cembra* as possible. *P. Cembra* is a very compact hardy tree, casting a dense shade, and although it grows very slowly it produces excellent wood, superior in every way to that of the Larch, while the seeds afford valuable and much esteemed food to our mountain population. With the *P. Cembra* the Spruce, *Picea excelsa*, can be planted; this tree also, although it grows naturally at rather lower elevations, supports the climate of high altitudes, while the Fir, *Abies pectinata*, is not found at high elevations in the Alps. With the Pyrenean Pine, *Pinus montana*, we have then three species to mingle with the Larch to create a forest able to resist the attacks of this fatal butterfly. M. Coax believes that the actual forests of pure Larch in Switzerland are not natural, but have been produced artificially by cutting the ancient mixed woods. On the ground left open by these cuttings it is the Larch which has succeeded so well that it has gradually taken possession of the whole ground. It is necessary, therefore, he believes, to restore, artificially, the ancient and natural condition of the forest.

Phlox divaricata on the Prairies.

To the Editor of GARDEN AND FOREST :

Sir,—Allow me to say, with reference to the remarks of Mr. Chamberlain, on page 209, that I have collected *Phlox divaricata* this spring on dry upland prairie, in poor soil and quite unshaded. This is, certainly, not its usual choice; but in one instance in particular I found an abundance of it growing as described. I have several times collected it in similar situations in Kansas and Oklahoma. I think this is about its western limit. It is moderately abundant as far west as Fort Riley, Kansas, but I have never seen it west of that point.

Coreopsis grandiflora, spoken of by Mr. Craig in the same number, page 208, is just now—May—in full bloom and in great abundance on the prairies here. It is one of the finest of prairie flowers and a general favorite among our many neighbors, whose only garden is the hills and whose gardener is nature. Even in stunted wild specimens the stems are long and the blossoms work up into bouquets with remarkable ease and success.

Does Poison Ivy Discriminate?

To the Editor of GARDEN AND FOREST :

Sir,—Whenever I see a tree in the embrace of a Poison Ivy I take my knife and cut the vine. On the grounds of a few friends and on my own I have cut vines from one and a half to two and a half inches thick, sometimes at the root and sometimes as far up as I could reach, and then tearing down the stems, have uprooted them with my hands. I have done this at all seasons. This spring I have already cut out two dozen Ivies, and have pulled up many others by the roots when my hands were torn by Blackberry thorns, but I never had a trace of poisoning. A friend to whom I mentioned my immunity said, "Of course you are not poisoned, because you are dark." Since then I have been thinking that in the cases of poisoning which had come to my knowledge the victims had been light-haired. A younger brother of mine, who is very fair, has been severely poisoned.

I. Ten Bosch.

When is Rhus toxicodendron Most Active?

To the Editor of GARDEN AND FOREST :

Sir,—The Poison Ivy, *Rhus toxicodendron*, should be avoided at all times of the year, in winter as well as in summer. I make this statement without qualification because I have suffered so frequently from attacks of dermatitis venenata, and I can remember no season since 1876, when I first became acquainted with the plant and had my eyes swelled shut, that I have not had, at least, two or three attacks.

Dr. Havard's remarks (page 203) interested me very much, and I, therefore, desire to give my experience as to this worst of poisonous plants, because it is so common and so universally distributed. Several years ago in January I was walking in Fairmount Park and saw a tree up which was clambering a huge Poison Ivy, at least an inch and a half in diameter. I decided to destroy the plant, at least for a while, by severing

the upper part from the roots. I took a stone and divided the stem by hammering it with a sharp rock which I held in my hand. Some of the juice must have touched my hands, for in a few days I had all the symptoms of *Rhus* poisoning. Since then I have been poisoned several times in winter by laying hold of the plants while out in the fields gathering seeds and capsules for class-work. The white fruits, when not eaten by crows, remain on the plants sometimes until next spring, so that I am quite sure of them.

To sum up in a few words, I have experienced the worst attacks in the months of August and September when the vegetation is rank and the plant is growing vigorously. I have also noticed that in warm autumn weather one is more subject to the poison when actively perspiring.
